#### Abstract

This paper studies the continuum and emission-line properties of a sample composed of 16 normal Seyfert 1 and seven narrow-line Seyfert 1 (NLS1) galaxies using optical and near-IR CCD spectroscopy. The continuum emission of the galaxies can be described in terms of a combination of stellar population, a nonstellar continuum of power-law form, and Fe II emission. A significative difference in the optical spectral index between NLS1's and normal Seyfert 1's is observed; the latter is steeper. Most NLS1's show Fe II $/ \mathrm{H} \beta$ ratios larger than those observed in the other Seyfert 1's. In the $I R A S$ band, both groups of galaxies have very similar properties. We have searched for the presence of optically thin gas in the broad-line region (BLR) of the galaxies by comparing the broad O I $\lambda 8446$ and $\mathrm{H} \alpha$ emission-line profiles. Our analysis show that in the NLS1's, both profiles are similar in shape and width. This result contradicts the hypothesis of thin gas emission in the high-velocity part of the BLR to explain the "narrowness" of broad optical permitted lines in these objects. Evidence of narrow O I $\lambda 8446$ emission is found in six galaxies of our sample, implying that this line is not restricted to a pure BLR phenomenon. In the narrow-line region, we find similar luminosities in the permitted and high-ionization lines of NLS1's and normal Seyfert 1's. However, low-ionization lines such as [O I] $\lambda 6300$, [O II] $\lambda 3727$, and [S II] $\lambda \lambda 6717,6731$ are intrinsically less luminous in NLS1's. Physical properties derived from densityand temperature-sensitive line ratios suggest that the [O II] and [S II] emitting zones are overlapping in normal Seyfert 1's and separated in NLS1's.

Subject headings: galaxies: nuclei - galaxies: Seyfert - X-rays: galaxies

## 1. INTRODUCTION

Nuclear emission-line spectra of Seyfert 1 (Sy1) galaxies are mainly characterized by the presence of broad permitted lines with typical full width at half-maximum (FWHM) between 4000 and $10,000 \mathrm{~km} \mathrm{~s}^{-1}$ and narrow permitted and forbidden lines with FWHM in the interval $300-900 \mathrm{~km}$ $\mathrm{s}^{-1}$. The former lines originate in the innermost central region ( $<1 \mathrm{pc}$ in size), the so-called broad line region (BLR), while the later are formed in the outer, more extended ( $\sim 100 \mathrm{pc}$ ), narrow-line region (NLR).

In addition, there is a peculiar group of AGNs known as narrow-line Seyfert 1 (hereafter NLS1) galaxies, located at the lower end of the broad line width distribution, with permitted lines having a FWHM in the interval 1000-2000 $\mathrm{km} \mathrm{s}^{-1}$. In most other properties, NLS1's are similar to "normal" Seyfert 1's except in the soft X-ray band, where they have generally much steeper continuum slopes and present in a few cases rapid variability (Boller, Brandt, \& Fink 1996). In the optical, their Fe II emission is among the strongest detected in AGNs.

The narrowness of the broad permitted lines in NLS1's is usually interpreted as a combined effect between a particular geometry of the emitting clouds and an orientation

[^0]effect. If the clouds are arranged in a planar geometry with its rotating axis almost parallel to the line of sight, the observed radial velocity distribution would be smaller (pole-on model; Boller et al. 1996).

However, Rodríguez-Pascual, Mass-Hesse, \& SantosLléo (1997) report the detection in NLS1 galaxies of broad components with FWHM around $5000 \mathrm{~km} \mathrm{~s}^{-1}$ in highionization UV permitted lines such as Ly $\alpha$, He II $\lambda 1640$, and C iv $\lambda 1550$. This result indicates that gas moving at velocities comparable to those found in typical Sy1 galaxies does indeed exist in NLS1's. The absence of broad lines (that is, lines with FWHM larger than $3000 \mathrm{~km} \mathrm{~s}^{-1}$ ) seems then to be restricted to the optical permitted lines.

While most efforts have been devoted to explaining the narrowness of broad permitted lines and the X-ray properties in NLS1's, very little has been said regarding the properties of the NLR in these objects. It is known that NLS1's usually have [O III] $\lambda 5007 / \mathrm{H} \beta<3$, much smaller than that in Seyfert 2 galaxies, and strong forbidden lines of highly ionized atoms. Except for a few spectral studies (Osterbrock \& Pogge 1985; Goodrich 1989; Stephens 1989) no quantitative analysis involving NLR emission-line ratios and a comparison to those of "normal" Sy1's have been done so far. For this reason, we have carried out a spectroscopic study of 23 galaxies, seven of which are classified as NLS1's and the remaining ones as " normal" Sy1's.

It is important to note that the adjective "normal" is used only as a semantic discriminator, and it implies Seyfert 1 galaxies with FWHM larger than $3000 \mathrm{~km} \mathrm{~s}^{-1}$ in the permitted lines. We are aware both of the wide heterogeneity of Sy1's as well as the fact that the properties of

NLS1's and normal Sy1's probably form a continuous distribution.

The present paper is organized as follows. In $\S 2$ we give a description of the observations and reduction procedure. Section 3 discusses the properties of the optical and IR continuum of the sample. The measurement and analysis of the line fluxes and line profiles is carried out in § 4, and the study of the NLR of the galaxies is given in $\S 5$. Our conclusions are in $\S 6$. A value of the Hubble constant of $H_{0}=75$ $\mathrm{km} \mathrm{s}^{-1} \mathrm{Mpc}^{-1}$ has been assumed throughout.

## 2. OBSERVATIONS AND DATA REDUCTION

The sample of Sy1 galaxies chosen for this study was taken primarily from the Calán-Tololo Survey (Maza et al. 1989, 1992, 1994) for two reasons. First, it is mainly composed of objects with little or no information available in the literature since they were classified as Sy1's recently. In this sense, they form an unexplored and valuable set of data, with some of the galaxies displaying very interesting spectral features. Second, the FWHM of the permitted emission lines forms a natural continuous sequence varying from 3000 up to $7000 \mathrm{~km} \mathrm{~s}^{-1}$, allowing the search for differences between emission-line properties of the NLR in NLS1 and Sy1 galaxies. The targets were selected from a list of more than 100 candidates. The only constraints applied were that the visual magnitude was brighter than 17 (to avoid long exposure times) and that the object had not been extensively studied in the optical region.

The NLS1 sample (Mrk 1239, 1H 1934-063, CTS R12.02, CTS J04.08, CTS J13.12, CTS J03.19, and CTS H34.06) is composed of objects that are typical representative of its class. The first four galaxies have available data in the $I R A S$ bands and soft X-ray region. CTS J04.08, CTS J13.12, CTS J03.19, and CTS H34.06 were classified as

NLS1 by us based on the appearance of their optical spectrum. Except for CTS J04.08, they have no published data in the literature.

The fundamental properties of the galaxies, obtained from the NED ${ }^{5}$ database, are listed in Table 1.

Long-slit spectra were obtained with the 2.15 m telescope of the Complejo Astronómico El Leoncito (CASLEO) during many observing runs using a TEK $1024 \times 1024$ CCD detector and a REOSC spectrograph. A $\log$ of the observations is given in Table 2. Two gratings of 300 line $\mathrm{mm}^{-1}$ with blaze angles near 5500 and $8000 \AA$ were used in order to cover the spectral interval $3700-9500 \AA$. The spatial scale of this setup is 0.95 pixel $^{-1}$, with a resolution of $4 \AA$ pixel $^{-1}$. In all cases it was employed a slit width of 2 " 5 oriented in the east-west direction. The galaxies and standard stars were observed near the zenith (air masses $<1.2$ ). The typical length of the spectral extraction window for the objects was between the four and eight innermost central pixels, depending on the seeing conditions during the observations. Atmospheric absorption bands were removed by dividing the object spectra by a smoothed and spline-fitted (but retaining the atmospheric bands) flux curve derived from a standard star spectrum observed at similar zenith distance to that of the object.

Data reduction was performed with standard IRAF ${ }^{6}$ tasks. The spectra were calibrated in wavelength using comparison lamps of $\mathrm{He}-\mathrm{Ne}-\mathrm{Ar}$, taken at the beginning and end of each object exposure. In all cases, the rms values of the wavelength calibration were less than $0.1 \AA$.

Flux calibration was carried out using observations of standard stars of Stone \& Baldwin (1983) taken at the beginning, middle, and end of each night. In order to link up the intensity scale in the optical and near-IR in each galaxy, we used the strongest common lines that could be identified and measured in the overlapping regions of the spectra. Care was taking in obtaining both spectra on consecutive nights in order to obtain a good match between the optical and near-IR regions.

The spectra were corrected for redshift derived from the strongest narrow emission lines observed. Usually [O III] $\lambda 5007, \mathrm{H} \alpha, \mathrm{H} \beta,\left[\mathrm{O}_{\mathrm{I}}\right] \lambda 6300$, and [S II] $\lambda \lambda 6717,6731$ were used for this purpose. The results are in very good agreement to those published in the literature. The radial velocity measured for each galaxy is listed in column (4) of Table 1. Galaxies marked with footnote a have no previous measurement of $V_{r}$. The size of the observed region (in kpc ) is listed in column (6).

Figure 1 presents the spectra of the 23 galaxies observed, already corrected for redshift and in increasing order of right ascension. NLS1's are identified from the remaining normal Sy1 galaxies.

## 3. CONTINUUM DECOMPOSITION

Before measuring the flux of the emission lines, it is necessary to determine and subtract the components of the observed continuum given that it affects the determination of the true level of the base of the lines as well as the form and width of the emission-line profiles. Such is the case of the $\mathrm{H} \beta+[\mathrm{O}$ iII $] \lambda \lambda 4959,5007$ blend, which is affected by the presence of the Fe II emission located under and at both sides of these lines, or the $\mathrm{H} \gamma+[\mathrm{O}$ III $] \lambda 4363$ lines, whose flux can be overestimated if the stellar continuum is strong.

We first searched for signatures of underlying stellar population from the host galaxy, whose contribution must be determined and subtracted in order to get a pure nuclear continuum. This can be carried out by measuring the equivalent width of absorption features such as Ca II K $\lambda 3933$, CN G $\lambda 4301$ and $\mathrm{Mg}+\mathrm{MgH} \lambda 5175$ following the method and templates described in Bica (1988). In CTS M17.17, CTS R12.15 and MCG -5-13-17, it was found that $60 \%$, $70 \%$, and $44 \%$, respectively, of the continuum at $5870 \AA$ was of stellar origin. The template that best reproduced the stellar populations in these galaxies was the S6, which is representative of stellar population with important contribution ( $\sim 25 \%$ ) of young stars with age $<5 \times 10^{7} \mathrm{yr}$.

In the remaining AGNs, the absorption bands were diluted by the strong nuclear continuum. We determined that the contribution of the stellar light to the observed continuum at $5870 \AA$ in these objects was no higher that $10 \%$. No effort was made to subtract the stellar population from them.

A nonstellar continuum of power-law form was also observed in most spectra. The task nfit1d of the STSDAS package of IRAF was used to fit a function of the type $F_{\lambda}=K *\left(\lambda / \lambda_{\text {ref }}\right)^{\alpha}$ to the observed continuum. In the above relation, $K$ (the amplitude of the power law at the reference wavelength $\lambda_{\text {ref }}$ ) and the spectral index $\alpha$ are parameters to be determined from the fit. $\lambda_{\text {ref }}$ was set to $4780 \AA$. In order to obtain a good fit, regions free of emission lines such as $4780 \AA, 5400 \AA, 5900 \AA$, redward of $\mathrm{H} \alpha$, and $7500 \AA$ were chosen as reference points. Column (9) of Table 5 lists the values of $\alpha$ found from the fit. A clear difference between the power-law index in NLS1 and

Fig. 1.-Spectra of the observed galaxies, in increasing order of right ascension, already corrected for redshift. Narrow-line Seyfert 1 galaxies are identified from the normal Sy1 galaxies.
normal Seyfert 1 galaxies is observed, with normal Sy1's usually presenting steeper slopes. The average value of $\alpha$ is -0.59 for NLS1's, -0.90 for normal Sy1's, and -0.79 for the whole sample. This result contrasts with what is reported in the X-ray spectral region, where NLS1's usually have steeper X-ray continuum slopes than normal Sy1's. However, we have to treat the above figures with caution owing to the small number of objects in our sample.

Some of the galaxies also show a pseudocontinuum created by the blending of several $\mathrm{Fe}_{\text {II }}$ multiplets. It is evident as two bumps centered at 4570 and $5250 \AA$ and is particularly strong in NLS1's, where Fe iI $\lambda 4570 / \mathrm{H} \beta$ is usually larger than 0.8 (Boller et al. 1996). As a comparison, the median value of the distribution of this ratio in the AGN sample of Joly (1991) is about 0.53 .

In order to quantify and subtract this component, we followed the procedure employed by Rodríguez-Ardila, Pastoriza, \& Maza (1998), consisting of estimating the
strength of the Fe II lines in the optical region using the spectrum of Zw 1 as a template. This NLS1 galaxy is widely known for having a very strong Fe II spectrum, which can be isolated and then scaled up to match the observed Fe if emission.

The Fe II $\lambda 4570 / \mathrm{H} \beta$ ratio found in each object is listed in column (8) of Table 5. Average values of this ratio are 0.92 and 0.53 for NLS1's and normal Sy1's, respectively. These numbers are in accord with the values reported in the literature and clearly reflect the fact that NLS1's are stronger Fe il emitters. In terms of frequency, all of our NLS1 galaxies show Fe II emission, in contrast to the $44 \%$ observed in normal Sy1's.

### 3.1. Infrared Properties of the Sample

We have used the $12 \mu \mathrm{~m}, 25 \mu \mathrm{~m}, 60 \mu \mathrm{~m}$, and $100 \mu \mathrm{~m}$ IRAS fluxes of the galaxies, listed in Table 3, to analyze the nature of the infrared emission in these objects. In particu-

Fig. 1.-Continued
lar, we wish to determine if the observed fluxes result from dust directly heated by the active galactic nucleus (warm dust), from the host galaxy (cool dust), or a combination of these two processes.

For this purpose we have calculated the $\alpha(25,12)$ and $\alpha(100,60)$ color indices using the expressions given in Bonatto \& Pastoriza (1997, hereafter BP97). The results are listed in columns (7) and (8) of Table 3. These colors are intended to estimate the effect of a cool dust component on Seyfert pure color indices, taking into account the fact that in normal spiral galaxies the observed $60 \mu \mathrm{~m}$ and $100 \mu \mathrm{~m}$ fluxes can be almost entirely accounted for by a combination of relatively cool ( $20-25 \mathrm{~K}$ ) dust heated by the interstellar radiation field and warmer dust heated by O and B stars (Walterbos \& Greenwalt 1996).

As a first result, NLS1's and normal Sy1's have very similar behavior. They share the same loci of points as the Seyfert 1 galaxies of BP97 (see Fig. 4 of BP97 and our values of color indices of Table 3). This indicates that the IR colors of our sample can be explained as a result of dust
heated directly by the AGN source with some fraction of emission from cool dust $(0.2 \leq \beta \leq 0.6)$ with evaporation temperature of $T_{e v}=1500 \mathrm{~K}$. The only exception is 1 H $2107-097$, which shows $\alpha(100,60)=-3.9$, indicating that it is redder than the remaining objects, with a strong contribution of cool dust at $12 \mu \mathrm{~m}(\sim 10 \%)$.

Regarding to the total infrared luminosity, we also found no significative differences between the values of $L_{\mathrm{IR}}$ displayed by both groups, as can be seen in the last column of Table 3.

## 4. THE EMISSION-LINE SPECTRUM AND EMISSION-LINE PROPERTIES OF THE GALAXIES

The integrated flux of the emission lines were measured assuming that they were well represented by Gaussian profiles. The LINER routine, a $\chi^{2}$ minimization algorithm that fits as many as eight Gaussians to a line profile, was used for this purpose. For heavily blended lines such as $\mathrm{H} \alpha+[\mathrm{N}$ II $]$ or $\mathrm{H} \beta+[\mathrm{O} \mathrm{III}]$, theoretical line ratios and known fixed wavelength separations between forbidden lines were

Fig. 1.-Continued
employed to constrain the fit. In some cases it was necessary to fit up to three Gaussians to the permitted lines in order to match satisfactorily the synthetically calculated profile to the observed one.

Figure 2 shows an example of the deblending process applied to the $\mathrm{H} \alpha+\left[\mathrm{N}_{\mathrm{II}}\right] \lambda \lambda 6548,6584$ lines of the NLS1 galaxies CTS J04.08 (a) and Mrk 1239 (b) and the normal Seyfert 1 galaxies CTS J15.22 (c) and CTS J04.08 (d). The wavelength axis is in velocity space, with $V_{e}=0$ representing the rest wavelength of $\mathrm{H} \alpha=6563 \AA$. Although not evident at first sight, it can be seen that in the former two galaxies there is a broad component with FWHM near $2000 \mathrm{~km} \mathrm{~s}^{-1}$, not as broad as those clearly observed in the normal Seyfert 1's. Note also that in the NLS1's, most of the core of $\mathrm{H} \alpha$ is dominated by a component of FWHM very similar to that of the forbidden lines [N II] $\lambda \lambda 6548,6584$. A comparison of the width of the narrow lines in the four panels allows us to associate the narrow $\mathrm{H} \alpha$ line in NLS1's with emission from the NLR. Figure 2 also shows that it is possible to carry out a clean separation between the "broad" and narrow components in NLS1's, provided the
signal-to-noise ratio $(\mathrm{S} / \mathrm{N})$ of the spectra is good, as it is the case.

The $\chi^{2}$ residuals of the Gaussian fits were $\sim 1 \%$ for strong lines and $\sim 5 \%-10 \%$ for weaker ones. Lines of ions such as [Fe x] $\lambda 6371$, [Fe viI] $\lambda 6085$, and most near-IR lines have rms values somewhat larger, and their fluxes are accurate only to within $10 \%-30 \%$. Tables 4 and 5 give the measured narrow- and broad-line fluxes, respectively. Note that $[\mathrm{O} \quad \mathrm{II}] \quad \lambda 3727=(\lambda 3726+\lambda 3729)$ and $[\mathrm{O} \mathrm{II}]$ $\lambda 7325=(\lambda 7320+\lambda 7330)$.

The last column of Table 4 lists the $E(B-V)$ determined from the Balmer decrement $\mathrm{H} \alpha / \mathrm{H} \beta$ assuming an intrinsic ratio of 3.1. In this calculation, only the flux of the narrow components were used. The $E(B-V)$ correction was not applied to broad line features because at the densities found in the BLR $\left(n_{e}>10^{9} \mathrm{~cm}^{-3}\right)$ many other processes different to pure recombination should affect the flux of the permitted lines.

The intrinsic FWHM values of $\mathrm{H} \alpha$ for the galaxies studied here are listed in Table 6. These values were obtained from the subtraction, in quadrature, of the

[^3]observed FWHM and that of the instrumental profile, measured from the comparison lamp lines (FWHM $\sim 360 \mathrm{~km}$ $\mathrm{s}^{-1}$ ). It can be seen than in NLS1's the FWHM of the broad component is clearly smaller than the typical FWHM of the broad lines of normal Seyfert 1 galaxies.

Usually the broad-line flux of the permitted lines in NLS1's is comparable to the flux of the narrow component, contrary to what is observed in normal Sy1's, where nearly $90 \%$ of the flux of a given Balmer line is associated to the BLR. In column (4) of Table 6 we have listed the ratio between the narrow and broad fluxes found for $\mathrm{H} \alpha$. Almost all NLS1's have ratios around 1, while in some normal Sy1's, it goes down to 0.04 .

### 4.1. Evidence of Optically Thin Gas in the BLR of Seyfert 1 Galaxies

The absence of broad permitted lines (i.e., lines with FWHM larger than $3000 \mathrm{~km} \mathrm{~s}^{-1}$ ) in NLS1's can be interpreted as being due to absence of gas moving at high velocity (in the line of sight) in the BLR of these objects. Osterbrock \& Pogge (1985), Goodrich (1989), Stephens (1989), and Puchnariewitz et al. (1992) argue that if the BLR clouds are confined to move in a plane, the emission lines will be narrower when the line of sight is nearly aligned with the axis of that plane. Another possibility is that NLS1's have central black hole masses smaller compared to those in normal Sy1's (Ross \& Fabian 1993). If the kinematics of the BLR is dominated by the central black hole, smaller masses would result in lower cloud velocities provided these clouds are located at distances similar to those in normal Sy1's.

However, Rodríguez-Pascual et al. (1997) report the detection of broad wings in the UV emission lines Ly $\alpha$, He iI $\lambda 1640$, and C iv $\lambda 1550$ of many NLS1 galaxies detected by the IUE at sufficiently high $\mathrm{S} / \mathrm{N}$. This finding demonstrates the existence of gas with a large velocity component in our line of sight, implying that the profiles are qualitatively similar to those found in normal Seyfert 1's. They explain the narrowness of broad optical lines as being due to the
absence of a hydrogen partially ionized (HPI) zone in the high-velocity component of the BLR in NLS1's.

The above means that high-ionization lines such as He II $\lambda 1640$ and C iv $\lambda 1550$ would display broad components in the spectrum, while low-ionization lines (H i Balmer lines) do not. H Ly $\alpha$ may form in both HPI or hydrogen fully ionized zones, explaining the presence of broad components in this line. The absence of an HPI zone means that the hydrogen is optically thin to the Lyman continuum photons. It is then necessary to look for evidences of optically thin gas in the BLR of Seyfert 1 galaxies to obtain additional evidence of this scenario. This can be done by comparing the $\mathrm{H} \alpha$ and $\mathrm{O}_{\text {I }} \lambda 8446$ emission-line profiles.

O I 28446 can be produced by several mechanisms such as recombination, collisional excitation, continuum fluorescence, and Ly $\beta$ fluorescence (Grandi 1980). The first two mechanisms require the presence of O I $\lambda 7774$ in the spectrum, while the third one requires the presence of O I $\lambda 7002$ and $\mathrm{O}_{\mathrm{I}} \lambda 7524$. Ly $\beta$ fluorescence, on the other hand, does not require the production of $\mathrm{O}_{\mathrm{I}} \lambda 7774, \lambda 7002$, and $\lambda 7524$, so their absence is a good indicator of the predominance of this mechanism as the most probable means for the $\mathrm{O}_{\mathrm{I}}$ $\lambda 8446$ emission. It takes advantage of the near coincidence of the energy levels of $\mathrm{H}_{\mathrm{I}}$ and O I and consists of a cascade following fluorescent absorption of Ly $\beta$ (see Fig. 3 of Grandi 1980). This mechanism requires large optical depths in Ly $\alpha\left(\geq 10^{7}\right.$; Elitzur \& Netzer 1985) in order to allow its eventual absorption by an $\mathrm{O}_{\mathrm{I}}$ atom in the ground state and prevent the conversion of Ly $\beta$ to Ly $\alpha$ and $\mathrm{H} \alpha$.

Assuming that the $\mathrm{H} \alpha$ line is produced by recombination and the BLR is composed of only optically thick clouds spread over a range of radii, with different velocities, this implies that $\mathrm{H} \alpha$ and O I 28446 should share the same emission-line profile. Otherwise, the presence of significant population of optically thin clouds (i.e., Ly $\alpha$ with optical depths $\ll 10^{6}$ ), would produce $\mathrm{H} \alpha$ emission, but not O I 28446. Thus, any profile differences between O i $\lambda 8446$ and $\mathrm{H} \alpha$ could be taken as evidence for optically thin gas in the BLR (Morris \& Ward 1989).

[^4]In Figure 3 we plot $\mathrm{H} \alpha$ (thick line) and O I 28446 (thin line) for the galaxies in which both profiles are observed. They have been normalized to unity and binned to velocity space. In all cases [N II] $\lambda \lambda 6548,6584$ were removed from $\mathrm{H} \alpha$ but the narrow component of the Balmer line was kept in order to look for narrow O I 28446 emission. The bump in the red wing of O I in $1 \mathrm{H} \mathrm{1934-063}$ is attributed to Ca II 28498. This emission line is part of the Ca II triplet and is produced in a region with high density and low ionization, as O I $\lambda 8446$. Ca II emission is not so common, and it has been observed in other Seyfert 1's but rarely in Seyfert 2's (Persson 1988; González Delgado \& Pérez 1996).

A detailed inspection to the profiles of Figure 3 allows us to conclude the following:

1. $\mathrm{H} \alpha$ and О I $\lambda 8446$ have similar line profiles in all but one of the objects studied. This suggests either that optically thin material contributes a negligible amount of the $\mathrm{H} \alpha$ emission or that the optically thin material shares the same spatial distribution and velocity field as the optically thick material. Only in CTS J07.02 is there evidence for differences between the two profiles. The narrow component of O i seems narrower than $\mathrm{H} \alpha$, and most important, its broad profile lacks the extended wings displayed by $\mathrm{H} \alpha$. These differences can be interpreted as evidence for the presence of thin gas that prevents the O I $\lambda 8446$ formation.
2. A narrow component associated with the O I 28446 emission is observed in most of the galaxies. In Mrk 1239, 1H 1934-063, and CTS J13.12, the presence of a narrow

component of $\mathrm{O}_{\mathrm{I}}$ is not evident, but it is certainly present given that the $\mathrm{H} \alpha$ and O I $\lambda 8446$ profiles are very similar and the narrow component of the former line was not removed. Only in 1H 2107-097 was no evidence of narrow a component for the O I found. Grandi (1980), Morris \& Ward (1989), and González Delgado \& Pérez (1996) had associated the O I $\lambda 8446$ emission with a purely broad-line phenomenon, and no narrow emission from this line was reported by them. In fact, in the profile comparison of Morris \& Ward (1989) no narrow profile in the O I $\lambda 8446$ line is seen, except in Mrk 1239, but the authors did not mention it explicitly.

The above results point out the presence of large optical depths in Ly $\alpha\left(\geq 10^{7}\right)$ in the BLR of $1 \mathrm{H} 2107-097$ and in both in the NLR and BLR of the remaining galaxies of Figure 3.

Based on the similarity of the line profiles of $\mathrm{H} \alpha$ and $\mathrm{O}_{\text {I }}$ for the NLS1's studied here, we can also conclude that no evidence of thin gas emission is found in the BLR of these objects. This result goes against the hypothesis of the lack of an HPI zone in the high-velocity gas to explain the absence of broad lines in our NLS1's. Another mechanism should be operating in these objects that prevents the broad components of the Balmer lines from being observed.

## 5. ANALYSIS OF THE NLR OF NLS1 AND NORMAL SY1 GALAXIES

The narrow line fluxes of Table 4 were corrected for reddening using the $E(B-V)$ values listed in the last column of that table. In this correction, the Cardelli, Clayton, \&

Fig. 2.-Deblending of the $\left.\mathrm{H} \alpha+\left[\mathrm{N}_{\text {II }}\right] \lambda \lambda 6548,6584\right]$ lines in the NLS1 galaxies CTS J04.08 (a) and Mrk 1239 (b) and normal Seyfert 1 galaxies CTS J15.22 (c) and CTS J14.05 (d) showing the decomposition into narrow and broad profiles (thin lines) using the Gaussian representation discussed in the text. The thick line shows the total fit, and the dotted line, the residuals of the fit. The feature longward of $6000 \mathrm{~km} \mathrm{~s}^{-1}$ are due to [S II] $\lambda \lambda 6717,6731$.

Mathis (1989) extinction function was used. The reddeningcorrected fluxes will be employed throughout this section to compare the emission properties of the narrow-line regions of normal Sy1 and NLS1 galaxies.

We have to stress here that given the good $\mathrm{S} / \mathrm{N}$ spectra of the NLS1's, it was possible to isolate the narrow component of the $\mathrm{H} \alpha$ line from the broad one in these objects (see $\S 4$ ). We associate the narrow profiles of the permitted lines with emission from the NLR because they have essentially the same width as that of the forbidden lines.

Figure 4 shows the $E(B-V)$ plotted against the FWHM of the broad component of $\mathrm{H} \alpha$ for our data. Filled triangles represent normal Sy1 galaxies and full circles NLS1 galaxies. Error bars are at $3 \sigma$ significative level. According to this figure, NLS1's tend to have lower values of reddening than normal Sy1's. We have found, on average, an $E(B-V)$ value of 0.46 mag for the former and 0.66 mag for the latter.

It is not possible to say if the continuum is affected by the same amount of reddening as the emission lines, but the fact of NLS1's having flatter optical spectral index than normal Sy1 galaxies suggests that their optical continuum may suffer of larger extinction.

It is also interesting to see how the featureless optical continuum at $4800 \AA$ correlates with the broad $\mathrm{H} \alpha$ luminosity, as is shown in Figure 5. We found that our galaxies follow the well-established correlation between line and continuum luminosity, determined by Yee (1980) and Shuder (1981), suggesting that the predominant mechanism of gas excitation in both NLS1 and normal Sy1 galaxies is photoionization.

### 5.1. Excitation of NLS1's and Normal Sy1's: What Does the Traditional Diagnostic Diagram Say

In Figure 6 we have used the diagnostic diagram [O III] $\lambda 5007 / \mathrm{H} \beta$ versus [ N II] $\lambda 6584 / \mathrm{H} \alpha$ of Veilleux \& Osterbrock (1987) to look for differences in the degree of excitation of the NLRs of the galaxies. It can be seen that both NLS1's and normal Sy1's are scattered across the diagram. Most "normal" Seyfert 1's (filled triangles) show line ratios typical of AGNs, while some others are located in transition zones normally occupied by starburst galaxies and H II regions. NLS1 galaxies (filled circles) are mainly located in the lower left-hand part of the figure, meaning that they are less excited than normal Sy1's. Stephens (1989) presented similar results for her sample of Seyfert 1 objects, but she employed the total flux of $\mathrm{H} \alpha$ and $\mathrm{H} \beta$ in the line ratios, causing the points to segregate naturally from the AGN region and fall in the lower left-hand corner of the figure. Here we show that even considering narrow-line fluxes in the permitted lines, there is a large spread of values for the line ratios involved and thus that diagram cannot be used to distinguish Seyfert 1 galaxies from other AGNs.

According to the unification model (Antonucci \& Miller 1985), the NLRs of Sy1 and Sy2 galaxies should have similar degrees of excitation. However, Figure 6 tells us that this may not be true. We find that the NLRs of Sy1 galaxies have line ratios that range from those of a typical $\mathrm{H}_{\text {II }}$ region up to those very similar to those of Seyfert 2's.

### 5.2. Other Line-Ratio Plots

Figures $7 a-7 f$ show [O II] $\lambda 3727 /[\mathrm{O}$ III $] \lambda 5007$, He II $\lambda 4686 / \mathrm{H} \beta$, [Fe x] $\lambda 6374 / \mathrm{H} \alpha$, [O iII] $\lambda 4363 /[\mathrm{O} \mathrm{III}] \lambda 5007$, [S II] $\lambda 6717+\lambda 6731 / \mathrm{H} \alpha$, and [O I] $\lambda 6300 / \mathrm{H} \alpha$ plotted against [O III] $\lambda 5007 / \mathrm{H} \beta$.

An inspection of the above plots allows us to say that NLS1 and normal Seyfert 1 galaxies appear to merge continuously with each other in most of the line ratios involved. This property is not restricted to the optical region. Boller et al. (1996) had also found the same result in their plot of the ROSAT $0.1-2.4 \mathrm{keV}$ photon index versus the FWHM of $\mathrm{H} \beta$. Also, Goodrich (1989) argued that the differences between NLS1 and normal Sy1 galaxies really represent a continuum of properties.

However, we found that in the diagrams involving low ionization lines, normal Seyfert 1's seem to cover a wider range of values than NLS1's. For example, in Figure 7e, no NLS1 galaxy has [S II] $\lambda 6717+\lambda 6731 / \mathrm{H} \alpha$ larger than 0.3 , while normal Seyfert 1 galaxies have values up to 0.9. Also, [O I] $\lambda 6300 / \mathrm{H} \alpha$ (Fig. $7 f$ ) is no larger than 0.1 in NLS1's, while in normal Seyfert 1's it goes up to 0.35 .

Fig. 3.-Comparison of the $\mathrm{H} \alpha$ (thick line) and $\mathrm{O}_{\text {I }} \lambda 8446$ (thin line) emission-line profiles in velocity space. The bump in the red wing of $1 \mathrm{H} 1934-063$ is due to Ca II $\lambda 8498$ emission.

When high-ionization lines are analyzed, as for example [Fex] $\lambda 6374 / \mathrm{H} \alpha$ versus [O III] $\lambda 5007 / \mathrm{H} \beta$ (Fig. 7c), we see that both groups of galaxies share the same range of values. Another good example is the ratio [O mil $\lambda 4363 /[\mathrm{O}$ mi $]$ 25007, which maps the temperature in the [ O mI ] zone. According to Figure 7d, NLS1's and normal Sy1's show no difference in temperature in the central parts of their NLRs.

In order to see if the above trends are observed in other NLS1s, we have plotted with crosses in Figures $7 a-7 f$ data for Mrk 42, Mrk 359, Mrk 493, Mrk 766, Mrk 783, and Mrk 1126, taken from Osterbrock \& Pogge (1985), and NCG 4253, taken from González Delgado \& Pérez (1996). It can be seen that these points also follow the same behavior as our NLS1s, giving additional support to our results.

Are [O I] $\lambda 6300 / \mathrm{H} \alpha$, [S II] $\lambda 6717+\lambda 6731 / \mathrm{H} \alpha$, and [O II] $\lambda 3727] / \mathrm{H} \beta$ intrinsically low in NLS1's, or are we seeing them as low because the Balmer emission lines are stronger
in these objects? In order to answer this question we have plotted in Figures $8 a-8 h$ several narrow-line luminosities versus the FWHM of the broad $\mathrm{H} \alpha$ line for the galaxies of our sample and those taken from the literature.

Figure 8 favors the interpretation that low-ionization lines are intrinsically weak in NLS1s. In Figure 8 $a$, we see that both groups of galaxies have essentially the same values of $\mathrm{H} \alpha$ luminosity, meaning that it is not a high $\mathrm{H} \alpha$ or $\mathrm{H} \beta$ in NLS1's that makes the above ratios smaller. Figures $8 c$ and $8 f$ separate NLS1's from normal Sy1's in the luminosity axis. In average, the [O I] $\lambda 6300$ and [O II] $\lambda 3727$ luminosity in NLS1's is smaller than in normal Sy1's. Other low-ionization lines such as [N II] $\lambda 6584$ and [S II] $\lambda \lambda 6717$, 6731 (Figs. $8 d$ and $8 h$, respectively), show the same behavior as [ $\mathrm{O}_{\mathrm{I}}$ ] $\lambda 6300$ and [ $\left.\mathrm{O}_{\mathrm{I}}\right] \lambda 3727$. The same can be said for [O III] $\lambda 5007$ (Fig. 8b), although this result was expected given that NLS1's are characterized by a low [O III] ג5007/

Fig. 4.-Plot of $E(B-V)$ vs. the FWHM (in $\mathrm{km} \mathrm{s}^{-1}$ ) of the broad component of $\mathrm{H} \alpha$. Filled triangles represent normal Sy 1 galaxies, and filled circles, NLS1 galaxies. The error bars are $3 \sigma$ significative.
$\mathrm{H} \beta$ ratio. [O III] $\lambda 4363$ has the opposite behavior, being stronger in NLS1's. For this reason, the [O III] temperatures in NLS1,s are nearly the same as those in normal Sy1's. High-ionization lines such as [Fe x] $\lambda 6374$ (Fig. 8e) do not differentiate between the two groups of galaxies.

### 5.3. Physical Conditions in the NLR

In this section we use the density indicator [S II] $16717 /$ [S II] $\lambda 6731$ and the temperature indicators [O II] $\lambda 3727 /$ [O II] $\lambda 7324$ and [O III] $\lambda 4363 /[\mathrm{O}$ III] $\lambda 5007$ to map the physical conditions inside the NLR of the Seyfert 1 galaxies of our sample.

Fig. 5.-Logarithm of the broad $\mathrm{H} \alpha$ luminosity (in units of ergs s ${ }^{-1}$ ) plotted against the logarithm of the continuum luminosity at $4800 \AA$, in units of ergs s ${ }^{-1} \mathrm{~Hz}^{-1}$. Symbols are the same as those of Fig. 4, and their sizes are, in all cases, representative of the error bar at $3 \sigma$ significative level.

Under normal photoionization conditions, [O II] $\lambda 3727$ and [S II] $\lambda \lambda 6717,6731$ are emitted in the same region because they have similar critical densities and ionization potentials. If these lines, along with [O II] $\lambda 7324$, are present in a given spectrum, it is possible to determine iteratively, without ambiguity, the density and temperature of the region in which they are formed. The procedure is as follows. An initial guess for the density is obtained using the [S II] ratio, assuming a temperature of, for example, $10^{4} \mathrm{~K}$. This density is then used to derive $T_{[\mathrm{O}}{ }_{\mathrm{I}]}$. If it differs from the initial value of $T$ by more than $5 \%$, a new $n_{e}$ is derived using the $T_{\left[\mathrm{O}_{\text {I] }}\right.}$ obtained in the previous step. The iteration continues until a convergence is reached, that is, until two consecutive values of $n_{e}$ and $T_{\left[\mathrm{O}_{\mathrm{II}}\right.}$ are very similar.

The above procedure were applied to 10 galaxies, and the results are listed in Table 7. In this calculation we used the task nebular of the STSDAS package of IRAF. Errors in the $T_{\left[\mathrm{O}_{\mathrm{II}}\right.}$ temperature are about 3000 K . Convergence was possible in four objects (CTS C16.16, MCG $-5-13-17$, Fairall 1146, and CTS J10.09). Average values for density and temperature are around $10^{3} \mathrm{~cm}^{-3}$ and $12,000 \mathrm{~K}$, respectively.

In four NLS1 galaxies (CTS H34.06, Mrk 1239, CTS J03.19, and 1H 1934-063) and one normal Sy1 galaxy (CTS A08.12), a first estimate of the density $n_{e}$ assuming a temperature of $10^{4} \mathrm{~K}$ gave no solution for $T_{\left[\mathrm{O}_{\mathrm{II}}\right.}$. In order to obtain $T_{\left[\mathrm{O}_{\mathrm{H}}\right.}$ values similar to those found in the first four galaxies (that is, $T_{\left[\mathrm{O} \mathrm{r}_{\mathrm{I}}\right.} \sim 12,000 \mathrm{~K}$ ), it was necessary to assume higher densities $\left(n_{e} \sim 5 \times 10^{3} \mathrm{~cm}^{-3}\right.$ to $3 \times 10^{4}$ $\mathrm{cm}^{-3}$ ) than those derived from the $[\mathrm{S} \mathrm{II}] \lambda 6717 / \lambda 6731$ ratio. This result suggests that in these objects, the [S II] and [ $\mathrm{O}_{\mathrm{II}}$ ] lines are not formed in the same region.

Table 7 also lists $T_{\left[\mathrm{O}_{\mathrm{m}}\right]}$, derived assuming electron densities of $10^{5} \mathrm{~cm}^{-3}$ (col. [4]) and $10^{6} \mathrm{~cm}^{-3}$ (col. [5]). Errors associated with $T_{[\mathrm{O} m]}$ are around 4000 K . In most cases, densities lower than $10^{5} \mathrm{~cm}^{-3}$ give temperatures larger than $6 \times 10^{4} \mathrm{~K}$, which are unlikely to exist in the NLR via photoionization by a central source.

It is possible to use $T_{[\mathrm{OIII}}$ to constrain $n_{e}$ in the [ O III ] zone using the fact that this temperature is not expected to be lower than $T_{\left[\mathrm{O}_{\mathrm{I}}\right]}$. For example, in CTS C16.16, $n_{e}$ is more likely to be around $10^{5} \mathrm{~cm}^{-3}$ since larger densities will produce a $T_{\left[\mathrm{O}_{\mathrm{II}]}\right.}$ lower than that of $T_{\left[\mathrm{O}_{\mathrm{I}}\right.}$. This density is in very good agreement with the results of Rodríguez-Ardila et. al. (1996), who found a density of $10^{5} \mathrm{~cm}^{-3}$ from photoionization modeling of that object. Here, we confirm their predictions using another approach. The same idea can be applied to MCG - 5-13-17, Fairall 1146, and CTS J10.09, where the $n_{e}$ in the [ O III] zone should be around $10^{5} \mathrm{~cm}^{-3}$. NLS1 galaxies as well as other normal Sy1's such as CTS M02.30, CTS J15.22 and 1H 2107-097 should have $n_{e}$ in the [ O III ] region $\geq 10^{6} \mathrm{~cm}^{-3}$. Lower values of density would raise $T_{\left[\mathrm{O}_{\mathrm{m}]}\right.}$ to extremely large values.

These results are in very good agreement with Figures 7d and $8 b$, where galaxies with large $\lambda 4363 / \lambda 5007$ ratios have low $\lambda 5007 / \mathrm{H} \beta$ ratios and intrinsic low $\lambda 5007$ luminosity. We have found that in these objects the density in the [O III] zone should be around $10^{6} \mathrm{~cm}^{-3}$. At this density, collisional de-excitation of [O III] $\lambda 5007$ is important, making this line appear quenched relative to [O III] $\lambda 4363$ and $\mathrm{H} \beta$.

Summarizing this section, our data suggest that a large range of densities, covering at least 4 orders of magnitude $\left(10^{2} \mathrm{~cm}^{-3}\right.$ to $\left.10^{6} \mathrm{~cm}^{-3}\right)$, must exist in the NLRs of Seyfert 1 galaxies. In normal Sy1's, the [S II] and [O II] regions are

Fig. 6.-[O III] $\lambda 5007 / \mathrm{H} \beta$ vs. [ N II $] \lambda 6584 / \mathrm{H} \alpha$ for the galaxies of our sample. Note that most NLS1 galaxies and some normal Sy1's are out of the region usually occupied by AGNs. $\mathrm{H} \alpha$ and $\mathrm{H} \beta$ correspond to the fluxes of the narrow components only.
overlapping and can be characterized by densities around $10^{3} \mathrm{~cm}^{-3}$ and temperatures near $12,000 \mathrm{~K}$. In NLS1's, these two regions seem to be separated, with typical densities near $5 \times 10^{2} \mathrm{~cm}^{-3}$ in the former and $10^{4} \mathrm{~cm}^{-3}$ in the latter. Deep into the NLR, where most of the [O III] emission and high-ionization lines are formed, densities larger than $10^{5}$ $\mathrm{cm}^{-3}$ and temperatures as high as $30,000 \mathrm{~K}$ can be found both in normal and NLS1 galaxies.

Among potential sources of uncertainties that can affect some of the results of the above sections we can list the following:

1. An inadequate subtraction of the stellar population that can lead to an overestimate of the flux in the $\lambda 4363$ line, giving a larger $T_{[\mathrm{O}}^{\mathrm{m}]}$.
2. Low $\mathrm{S} / \mathrm{N}$ spectra that can lead to an inadequate deblending of the $\mathrm{H} \gamma+$ [O III] $\lambda 4363$, affecting the flux of the latter line.
3. A bad $E(B-V)$ correction giving larger $T_{\left[\mathrm{O}_{\mathrm{I}}\right.}$ temperatures.
4. The presence of Fe II residual, even after subtraction of this continuum, since it interferes with the measurements of the [ O III] $\lambda 5007$ and [ O III] $\lambda 4363$ line fluxes.

However, we estimate that our data are not seriously affected by the above factors since a clean subtraction of the continuum components (see § 3) and a good separation of strong blended lines (see § 4) were carried out in most of the galaxies of our sample.

It is important to note that the above description is very simple and by no means describes the full range of physical conditions inside the NLRs of Seyfert 1 galaxies. Additional density- or temperature-sensitive ratios involving ions of higher ionization potential and/or critical densities are necessary not only to confirm our results but also to map whole range of temperatures and densities that seems to be present across the NLR.

## 6. SUMMARY AND CONCLUSIONS

We have carried out a spectroscopic study in the optical, near-IR, and IR bands of a sample composed of seven narrow-line Seyfert 1 and 16 normal Seyfert 1 galaxies in order to study the continuum and line emission properties of these objects. The following are the main results.

1. We have found from the optical continuum distribution that in CTS M17.17, CTS R12.15, and MCG -5-13-

Fig. 7.-Several narrow emission line ratios plotted against [O III] $\lambda 5007 / \mathrm{H} \beta$. Symbols are the same as Fig. 6. Crosses represent NLS1s taken from the literature (see text for more details). The error bars are $3 \sigma$ significative.

17 , the stellar population contributes $60 \%, 70 \%$, and $44 \%$, respectively, of the continuum at $5870 \AA$. For the remaining galaxies, the stellar population contribution to the total continuum is negligible. Differences in the power-law index $\alpha$ of the nonthermal continuum component are found between NLS1 and normal Sy1 galaxies, the latter objects usually presenting steeper slopes. Another important component of the observed continuum, mainly in NLS1's, is the Fe iI emission. Its contribution, quantified by the $\mathrm{Fe} \mathrm{II} / \mathrm{H} \beta$ ratio, is higher in NLS1's (0.92) than in normal Sy1's $(0.53)$
2. In the IRAS band, NLS1's and normal Sy1's have very similar behavior. The IR colors of our sample can be explained as a result of dust heated directly by the AGN source with some fraction of emission from cool dust $(0.2 \leq \beta \leq 0.6)$ with evaporation temperature of $T_{\mathrm{ev}}=1500$ K. The only exception is 1 H 2107-097, which shows $\alpha(100,60)=-3.9$, very reddish for Seyfert 1 objects.
3. We have searched for evidence of thin gas emission in order to explain the narrowness of the broad permitted lines in NLS1's. This can be done by looking for differences between the line profiles of $\mathrm{H} \alpha$ and O I $\lambda 8448$. Our results show that these two lines are rather similar except in CTS J07.02, a normal Sy1 galaxy. In addition, we find a narrow component associated with the O I $\lambda 8446$ emission in most
of the galaxies in which this line is present. This result suggests that the O I 28448 is not a purely broad-line phenomenon, as was previously considered.
4. From the diagnostic diagram [O III] $\lambda 5007 / \mathrm{H} \beta$ versus [ $\mathrm{N}_{\text {II }}$ ] $\lambda 6584 / \mathrm{H} \alpha$, we observed that Seyfert 1 galaxies show a large range of excitation, varying from that typical of AGNs to those usually observed by H II regions and starburst galaxies. NLS1's have a larger tendency to occupy the regions of the least excited objects.
5. The NLRs of narrow-line and normal Sy1 galaxies show important differences. Low-ionization lines such as [O I] $\lambda 6300$, [S II] $\lambda 6717+\lambda 6731$, and [O II] $\lambda 3727$ are intrinsically less luminous in the former than in the latter. When high-ionization lines are analyzed, for example [Fex] $\lambda 6374$, we see that both groups of galaxies are mixed and distributed uniformly. This is also true for $\mathrm{H} \alpha$. We do not find differences in temperature for the [ O III ] zone in NLS1's and normal Sy1's.
6. Our data suggest that a large range of densities, covering at least 4 orders of magnitude $\left(10^{2} \mathrm{~cm}^{-3}\right.$ to $\left.10^{6} \mathrm{~cm}^{-3}\right)$, must exist in the NLRs of Seyfert 1 galaxies. In Sy1's, the [S II] and [O II] regions are overlapping and can be characterized by densities around $10^{3} \mathrm{~cm}^{-3}$ and temperatures near $12,000 \mathrm{~K}$. In NLS1's, these two regions seems to be

Fig. 8.-Log of the luminosity (in ergs s${ }^{-1}$ ) of several narrow emission lines vs. the FWHM (in $\mathrm{km} \mathrm{s}^{-1}$ ) of the broad component of $\mathrm{H} \alpha$. Symbols are the same as Fig. 6. The error bar is in all cases smaller than the size of the points.

[^6]separated and characterized by different densities. Deep into the NLR, where most of the [O III] emission and highionization lines are formed, densities larger than $10^{5} \mathrm{~cm}^{-3}$ and temperatures as high as $30,000 \mathrm{~K}$ are found in both groups of objects. The low [O III] $\lambda 5007 / \mathrm{H} \beta$ found in most NLS1 and some normal Sy1's is most probably due to collisional de-excitation of [ O III ] $\lambda 5007$.
A. R. A. wishes to thank Cláudia Winge for very useful comments and suggestions and the staff of CASLEO Obser-
vatory for their hospitality and technical support during the observing runs. We thank the anonymous referee for useful comments that helped to improve the quality of this paper. This work has been partially supported by the Brazilian Research Council (CNPq) to A. R. A. This research has made use of the NASA/IPAC extragalactic data base which is operated by the Jet Propulsion Laboratory, Caltech.
