Vera Lúcia S. Valente³

ABSTRACT

Using conventional staining with acetic orcein and C-banding techniques it was investigated constitutive heterochromatin chromosomal polymorphisms and the mitotic and the meiotic behavior of male and female chromosomes of *Boophilus microplus* (Canestrini, 1887). Some differences were detected in the population of southern Brazil as compared to the data of other authors for populations in other latitudes. The differences being mainly concerned with the distribution of constitutive centromeric heterochromatin and variation in the length of heterochromatic blocks in the pericentromeric regions of some chromosome pairs.

KEYWORDS. Arachnida, Acari, chromosomes, C-banding, *Boophilus*.

INTRODUCTION

The only *Boophilus* species occurring in Brazil is *Boophilus microplus* (Canestrini, 1887), an Asian tick species which has been introduced into the majority of tropical and subtropical countries by the importation of Asian cattle. Infestation of cattle by the tick *B. microplus* results in economic damage due blood loss, transmission of Babesiosis and the serious damage caused to leather quality because of perforation of the hides during tick-feeding.

Cytogenetic studies have been conducted on several tick species, mainly concerning cytotaxonomy (KHAN, 1964) and the details of the meiotic events which occur during gametogenesis. OLIVER & BREMNER (1968) described the chromosome number of male and female *B. microplus*, establishing the sexual determination mechanism (XX:X0) and the acrocentric nature of the chromosomes. Other tick, *Ixodes ricinus* Linné, 1758, have a XX:XY type sexual determination mechanism in which the Y chromosome is very small, the mitotic metaphase X chromosome is invisible and a pair of chromosomes shows a

subterminal constriction in addition to the primary constriction (KAHN, 1964). These findings contradict the theory that an XX:XY sexual determination mechanism is common to all soft ticks (Agarsidae) while all hard ticks (Ixodidae) have an XX:X0 mechanism. In both families males are the heterogametic sex and the sexual chromosome is, in general, larger than the autosomes (OLIVER, 1965). The cytogenetic approach has also been applied to clarify the mechanisms involved in gamete formation during hybridization between related tick species. OLIVER & BRINTON (1972) described the male reproductive apparatus of *Dermacentor occidentalis* Marx, 1892 along with several stages of spermatogenesis but, other authors (NEWTON *et al.*, 1972; GUNN *et al.*, 1993) have encountered difficulties in recognizing prophase I in terms of the established Ixodidae pattern. The difficulties encountered in the interpretation of mitotic and meiotic patterns can be illustrated by the fact that very similar meiotic processes have been given different names in *Hemophysalis leporis palustris* Neumann, 1887 (KAHN, 1964) and *Argas persicus* Oken, 1818 (GOROSHCHENKO, 1960), while the stage known as diakinesis in *Boophilus annulatus* Say, 1821 (NEWTON *et al.*, 1972) spermatocytes has been interpreted by KAHN (1964) as Prophase II in *Ixodes ricinus*.

The similarity between the prophase II chromosome configurations of *B. microplus* and *B. annulatus* in Mexican *Boophilus* populations has been described by NEWTON *et al.* (1972), who noted that male X chromosomes are 1.5 to 4 times larger than the maximum length of mitotic autosomes and that there were chromatin connections between X chromosomes in mitotic anaphases and the precocious migration of sexual chromosomes during meiotic metaphase I. Karyotypic variation in meiotic chromosome length has also been observed in Australian *B. microplus* populations by OLIVER & BREMNER (1968), who stated that the male X chromosomes of these populations are 3 to 6 times larger than autosomes and the major autosomes twice the size of the minor autosomes. NEWTON *et al.* (1972) attributed these differences to technical problems, reporting that *B. microplus* and *B. annulatus* chromosomes gave indistinguishable karyotypes.

The southernmost Brazilian state, Rio Grande do Sul (RS), has a long history of cattle ranching which is important to the local economy. The uncertainty in the published research (carried out with *B. microplus* populations geographically distant from RS populations), the lack of information on karyotype configuration in *B. microplus* populations in RS, and the fact that the meiotic configuration of *Boophilus* females was unknown gave rise to characterize mitotic and meiotic chromosomal behavior in male and female *B. microplus* gonads. Thus, the aim was to investigate differences in the constitutive heterochromatin of the chromosomes of southern Brazilian *B. microplus* populations.

MATERIAL AND METHODS

Boophilus microplus ticks (10 adult males; 2 nymph males; 16 nymph females; 12 early engorged females) obtained from experimentally infested cattle reared in the Faculdade de Veterinária, UFRGS, Porto Alegre (30°2' S, 51°14' W), Rio Grande do Sul, Brazil, were cytologically examined. Ticks were placed in Shen saline (containing (g/l) NaCl, 9; KCl, 0.42; CaCl₂, 0.25) and dissected under a stereomicroscope, with the gonads being immediately transferred to a drop of 9% hypotonic sodium citrate solution placed on a glass slide which was then covered by a thin film of commercial gelatin and allowed to stand for 10 min, after which they were fixed in 3:1 ethanol:acetic acid solution for 3 min and squashed in 3% acetic orcein. The gonads of 8 females were C-banded using the method of GUNN & HILBURN (1989) in which the barium hydroxide exposure time had been modified (1 min was found to be ideal) and stained with buffered Giemsa for 15 min and photomicrographs for cytological analysis were taken using a photomicroscope and 100 ASA film. Karyotypes were formed by placing the chromosomes in decreasing order size using the criteria of HILBURN *et al.* (1989).

RESULTS

Mitosis was detected only in the nymphs of males and females (figs. 1-6) while different meiotic phases were only found in the gonads of adult males (figs. 7-14), although metaphases I, anaphase I and prophase II were not detected in the meiotic nuclei analyzed. Meiosis was not observed in the gonads of females. In two female nymphs it was possible to see bridges between the X chromosomes during mitotic anaphase (fig. 6), but no anomalous sexual chromosome migration was detected in any of the other mitotic cells analyzed.

No variation in *B. microplus* chromosomal number was found. In all the mitotic nuclei observed the X chromosomes were twice the length of the major autosomes (fig. 15), but this difference was not so pronounced in the meiotic nuclei (data not shown), where all X chromosomes appeared to be the same length as the autosomes. An extra-centromeric constriction was detected in autosome pair 3 (fig. 15).

The position of the centromere was not clearly defined by conventional staining, but C-banding showed both the acrocentric nature of the chromosomes and centromeric heterochromatic bands which appeared to be different among chromosomes, with chromosome pairs 4 and 6 containing large pericentromeric heterochromatic bands, while chromosome pairs 2, 5, 7, and 10 contain small heterochromatic bands. There were no heterochromatin polymorphisms between the individual chromosomes of each chromosome pair. Chromosome pairs were more easily recognized using C-banding and this allowed the construction of a schematic interpretation of the heterochromatin in the karyotype of *B. microplus* (fig. 16).

DISCUSSION

It was difficult to compare pictures of *Boophilus microplus* prophase I taken in the present study with those of different tick species and of those of *B. microplus* populations reported by other authors. This difficulty has already been reported in the Ixodidae by KAHN (1964) and OLIVER *et al.* (1974). The configurations described by KAHN (1964) as prophase II and metaphase II in Ixodidae, were similar to those interpreted by us as telophase II. We recognize as anaphase II meiotic configurations similar to those described by NEWTON *et al.* (1972) as diakinesis. In the cytological material here examined it was relatively easy to see that the chromatids segregated individually, without terminal chiasmata, and that the degree of coiling was compatible with its stage (anaphase II). Meiotic metaphase I, anaphase I and prophase II were not detected, probably because they are very short stages. The lack of meiotic cells in the gonads of *B. microplus* females in the samples, confirms the results of several other studies performed on various tick species (OLIVER & BRINTON, 1972; OLIVER *et al.*, 1974; OLIVER & OSBURN, 1977; GUNN *et al.*, 1993).

In previous *B. microplus* studies, we also observed a relationship between the start of tick feeding and the amount of blood available to the tick and the start of cellular division, a relationship also reported in *Otobius megnini* (Duges, 1883) and *O. lagophilus* Cooley & Kohls, 1940 by OLIVER & OSBURN (1977). No cellular divisions were detected by us in *B. microplus* eggs and larvae in the period before the ticks were added to the host and were consequently without food. A decrease in the amount of cellular divisions (mitosis) was also observed in partially engorged females. Some results in the literature indicate that the process of oocyte maturation in the reproductive tract of females is

complex (GARCIA *et al.*, 1993; GARCIA-FERNANDEZ *et al.*, 1996) and is synchronized with the ticks general metabolism. OLIVER (1965) stated that the chromosome number of most Ixodidae ticks is $2n=21$ for males and $2n=22$ for females, in agreement with we found in southern Brazilian *B. microplus* population. These chromosome number were also reported by NEWTON *et al.* (1972) for Mexican populations and by HILBURN *et al.* (1989) for southern USA populations.

Acetic orcein staining of mitotic chromosomes did not clearly detect the position of the centromere, something also noted in laboratory strains of *Amblyomma cajennense* Fabricius, 1787 (GUNN & HILBURN, 1991). C-banding, however, allowed us to confirm that all *B. microplus* chromosomes are acrocentric, as suggested by OLIVER & BREMNER (1968), a finding which suggests that no variation occurs in the chromosomal arrangements present in the southern Brazilian populations of *B. microplus* nor in those studied in different latitudes.

As was previously reported by NEWTON *et al.* (1972), we found little difference in length between meiotic autosomes themselves or between meiotic autosomes and X-chromosomes. Mitotic material allowed clearer differentiation of chromosomal pairs, and it was possible to observe that the larger autosomes were half of the length of the X-chromosomes. There was a secondary constriction in chromosome pair 3, as reported for one of the autosomes in Mexican *B. microplus* populations (HILBURN *et al.*, 1989). The function of the anaphase bridges observed in mitotic X-chromosomes is not clear, although this phenomenon has been reported by NEWTON *et al.* (1972) and apparently does not interfere with normal chromosomal segregation. This conclusion is reinforced by the fact that no supernumerary chromosomes were found in our material, something also noted by OLIVER *et al.* (1974) in Acari. The fact that the same findings have been detected by different authors working with populations from very different geographical regions suggests that the world-wide *B. microplus* population is quite uniform with respect to karyotype general organization.

The C-banding enabled us to investigate novel aspects of *B. microplis* constitutive heterochromatin. In the southern Brazilian population studied several other C-bands were recorded besides those already described for other *B. microplis* populations by HILBURN *et al.* (1989), who described two small heterochromatin blocks in chromosomal pairs 2 and 10 and a larger one in chromosome pair 4. GUNN *et al.* (1993) described a heterochromatin block in the centromeric region of the X chromosome. We encountered the same C-band pattern in all individuals analyzed, which allowed to discard the existence of intra-population structural polymorphism. Several studies (JOHN & KING, 1983; KENTON, 1991; ZHIMULEV, 1998) have reported the existence of polymorphism, which regard to the length and position of heterochromatic blocks between individuals of the same species as well as between individuals of related species.
