ABSTRACT

Extended narrow-line regions (NLRs) around active galactic nuclei (AGN) are shaped by the distribution of gas in the host galaxy and by the geometry of the circumnuclear obscuration, and thus they can be used to test the AGN unification model. In this work, we quantify the morphologies of the NLRs in 308 nearby AGN ($z = 0 - 0.14$, $L_{\text{bol}} \sim 10^{42.4 - 44.1} \text{ erg s}^{-1}$) from the MaNGA survey. Based on the NLR maps, we find that a large fraction (81 per cent) of these AGN have bi-conical NLR morphology. The distribution of their measured opening angles suggests that the intrinsic opening angles of the ionization cones have a mean value of $85^\circ - 98^\circ$ with a finite spread of $39^\circ - 44^\circ$ (1σ). Our inferred opening angle distribution implies a number ratio of type I to type II AGN of 1:1.6–2.3, consistent with other measurements of the type I/type II ratio at low AGN luminosities. Combining these measurements with the *WISE* photometry data, we find that redder mid-IR colour (lower effective temperature of dust) corresponds to stronger and narrower photoionized bicones. This relation is in agreement with the unification model that suggests that the bi-conical NLRs are shaped by a toroidal dusty structure within a few pc from the AGN. Furthermore, we find a significant alignment between the minor axis of host galaxy discs and AGN ionization cones. Together, these findings suggest that obscuration on both circumnuclear (\sim pc) and galactic (\sim kpc) scales is important in shaping and orienting the AGN NLRs.

Key words: galaxies: active – galaxies: general – galaxies: Seyfert – galaxies: structure.

1 INTRODUCTION

The unification scheme of active galactic nuclei (AGN; Antonucci 1993) was developed to resolve the dichotomy of AGN types with one geometrical model. The model posits that all AGN are fundamentally the same and are powered by a nucleus emitting featureless continuum and broad lines, which is embedded in a torus-like dusty structure. The two spectral types, broad line (type I) and narrow line (type II) AGN, arise depending on whether the observer has a direct view to the nucleus (type I) or the dusty torus blocks our line of sight

(type II). The viewing angle is the sole factor in determining the spectral type of the AGN, as the model presumes a universal dusty torus that is uniform, opaque, and has a fixed opening angle at any given AGN luminosity (Antonucci 1993). This model elegantly explains a number of observables, including the polarized continuum (Antonucci & Miller 1985), conical scattered light and narrow-line regions (NLRs; e.g. Evans et al. 1991; Mulchaey, Wilson & Tsvetanov 1996a,b; Zakamska et al. 2005; Obied et al. 2016), and dust emission in the mid-IR (Pier & Krolik 1992, 1993).

Even at a fixed luminosity, AGN differ in properties such as radio brightness or presence of outflows, so it is reasonable to expect variations in the dusty torus geometry as well. Evidence from optical and mid-IR observations suggests that AGN tend to have a range of torus covering factors (e.g. Müller-Sánchez et al. 2011;

* E-mail: zcho@jhu.edu (ZH); asun27@jhu.edu (A-LS); zakamska@jhu.edu (NLZ)

Ramos Almeida et al. 2011; Ichikawa et al. 2015; Audibert et al. 2016; García-González et al. 2017). It is important to quantify the distribution of the torus covering factor, because it can cause biases in AGN selection with respect to spectral types, in the sense that AGN with larger covering factors are more likely to be classified as type II and vice versa (Elitzur 2012). However, direct measurements of the distribution of the opening angle have been challenging.

Near-IR and mid-IR spectroscopic modelling of dust emission can constrain the covering factor to some extent but has strong degeneracies (Netzer 2015). Resolving the spatial structure of the torus has been limited to a handful of nearby systems, and even so their inner edge cannot be seen (e.g. Hoenig et al. 2010; Tristram et al. 2014). Currently, the best estimates rely on indirect methods, such as the ratio of hot dust emission to the AGN bolometric luminosity (L_{bol}), inferred from X-ray, optical, or both (e.g. Maiolino et al. 2007; Treister, Krolik & Dullemond 2008; Mateos et al. 2016; Ezhikode et al. 2017), but such measurements are subject to systemic uncertainties in inferring the total torus and AGN luminosity and depend on assumptions on their emission anisotropy.

Statistical studies of NLR morphology offer a promising approach to constrain the opening angle of the dusty torus and to test the unification model. Our group investigated 2727 galaxies from Mapping Nearby Galaxies at Apache Point Observatory (MaNGA) and developed spatially resolved techniques for identifying signatures of AGN (Wylezalek et al. 2017). A sample containing 308 type II AGN candidates was identified in Wylezalek et al. (2017) via the presence of photoionized gas. In this paper, we use their NLR morphology to test the AGN unification model. One of the challenges is the diverse morphology of these regions that makes it difficult to automate the classification of a cone-like or bi-polar structures and to measure their orientations and opening angles. In this work, we develop a measurement scheme to robustly identify ionization cones and to quantify their morphology, allowing statistical studies of this large sample.

In the unification model, a correlation between the NLR morphology and the mid-IR colour of dust emission is expected because both depend on the inclination of the system. When the torus is edge on, the observer can see the cone-like morphology of the NLR with the smallest projected opening angle. At the same time, the mid-IR colour of this object should be red, because the hotter dust closer to the centre is hidden behind the colder one on the outskirts, as predicted by a variety of torus models (Pier & Krolik 1992; Stalevski et al. 2012). As the torus becomes more face-on, the observed cone opening angle becomes larger due to projection effects, and eventually, the cones become indistinguishable producing halo-like shape (Mulchaey et al. 1996b). The mid-IR colours of these face-on objects are expected to be bluer because of the direct view to the inner hot dust. Fischer et al. (2013, 2014) have found correlation between mid-IR colour and NLR inclination based on kinematics modelling of bipolar outflows. In this work, we approach this question with resolved two-dimensional NLR morphology.

Furthermore, with resolved morphology, we can test the relation between the NLR and the host galaxy. The pc-scale dusty torus is not the only obscuring material to block the ionizing radiation of AGN. Structured dust, such as dust lanes, also exists on galactic scales, which has the same effect of obscuring radiation from the nucleus (Lagos et al. 2011; Goulding et al. 2012) and thus shaping the NLR. Therefore, it is important to test the degree of alignment between the NLR and the dusty torus as well as the alignment between the NLR and the galactic dust.

The paper is organized as follows: In Section 2, we describe MaNGA data and supporting multiwavelength observations. In Section 3, we describe our morphological measurements. In Section 4, we present our results on the intrinsic NLR morphology as well as the relationship between the NLR, dust emission, and the host galaxies. We discuss our results in Section 5 and conclude in Section 6. Wavelengths in vacuum are used for measurements of the Sloan Digital Sky Survey (SDSS) datasets, but we follow the long-established convention and denote emission lines with their air wavelengths (e.g. [OIII]5007 Å). Cosmology with $h = 0.72$, $\Omega_m = 0.3$, and $\Omega_\Lambda = 0.7$ is adopted throughout this paper. We define the inclination of the AGN system (NLR or dusty torus) as the angle between the polar axis and the line of sight (LOS).

2 DATA

2.1 Sample of MaNGA AGN and AGN narrow-line region maps

The SDSS-IV (Blanton et al. 2017) MaNGA (Bundy et al. 2014; Drory et al. 2015; Law et al. 2015; Yan et al. 2016a,b) is an optical fibre-bundle integral field unit (IFU) spectroscopic survey conducted with the 2.5 m Sloan Foundation Telescope (Gunn et al. 2006) and is one of the three major parts of the ongoing SDSS-IV. MaNGA uses the Baryon Oscillation Spectroscopic Survey spectrograph (Smee et al. 2013) with a spectral coverage of 3622–10354 Å at $R \sim 2000$. The diameters of the bundles range from 12 to 32 arcsec, corresponding to 23 to 61 kpc at redshift of 0.1.

Using the outputs from the MaNGA Data Analysis Pipeline, Wylezalek et al. (2017) utilize the traditional [NII] line-diagnostic diagram (Baldwin & Terlevich 1981; Veilleux & Osterbrock 1987; hereafter BPT diagram) and construct resolved BPT diagram maps for all galaxies in the MaNGA sample. The [NII]-BPT diagram allows us to distinguish between star formation, AGN, or composite (mix of AGN and star formation) dominated emission-line regions. From 2727 galaxies observed by MaNGA, Wylezalek et al. (2017) identified a sample of 308 type II AGN candidates, which has a redshift range of 0.008–0.14 and an [OIII] luminosity ($L_{[\text{OIII}]}$) range of $10^{39.3} - 10^{41}$ erg s⁻¹. In this paper, we focus on the resolved BPT-maps of this type II AGN sample. The spatial resolution of the map is typically 1–2 arcsec or 1–2kpc.

2.2 WISE mid-IR colours

In order to characterize the effective temperature of the dusty torus, we match our MaNGA AGN sample with the *Wide-field Infrared Survey (WISE)* photometry data from All *WISE* Source catalogue¹ (W1, 3.4 μm; W2, 4.6 μm; W3, 12 μm; W4, 22 μm). All sources have *WISE* matches within 10 arcsec, which is acceptable given the *WISE* spatial resolution (6–12 arcsec).

In addition to the thermal emission of dust at a wide range of temperatures, the mid-IR spectra of AGN are rich in features, such as silicates at 9.7 and 18 μm in emission or absorption and polycyclic aromatic hydrocarbon (PAH) features at 6.2, 7.7, 8.6, 11.3, and 12.7 μm. To minimize the impact of these silicate and PAH features, we choose the W2–W4 colour as a proxy to the temperature (and thus the inclination) of the dusty torus. The wavelength range of the *WISE* W2, W4 filters are ~ 4–5.5 μm and ~ 19–28 μm, respectively

¹<http://irsa.ipac.caltech.edu/cgi-bin/Gator/nph-dd>

(Wright et al. 2010), so the W2 and W4 filters avoid most of the spectral features.

The stellar emission in the host galaxy may contribute to the infrared radiation, so we estimate and subtract the stellar component by extrapolating the stellar emission in the optical. We obtain the SDSS *i* (centred at 7625 Å) and *z* (centred at 9134 Å) band photometry (PSF magnitude and Petrosian magnitude) for 290 of 308 objects by matching to the position of each object within a circle of 10 arcsec radius and $z < 0.15$ using the SDSS CASJOBS.² We use a Spiral 0 template from the SWIRE template library (Polletta et al. 2007) to extrapolate the stellar light to the mid-IR. We convert the Spiral 0 template flux into the corresponding magnitude of SDSS *i*, *z* and *WISE* W2, W4 bands. First, we convolve the template flux with the SDSS and *WISE* filter transmission function of SDSS *i*, *z* (Doi et al. 2010) and *WISE* W2, W4 (Wright et al. 2010) bands to calculate the corresponding flux density. For SDSS, we use the arcsinh conversion from Lupton, Gunn & Szalay (1999) to convert the flux into the magnitudes. For *WISE*, we convert the flux into the magnitude using the *WISE* zero-magnitude Attributes (Jarrett et al. 2011). The effective apertures used for deriving *WISE* magnitudes are likely larger than those of the SDSS PSF magnitudes and smaller than those of the Petrosian magnitudes. So, the PSF magnitude and Petrosian magnitude represent the full range of mid-IR colours corrections (PSF magnitudes underestimate the stellar contribution and Petrosian magnitudes overestimate the stellar contribution).

2.3 Host galaxy morphology from SDSS catalogues

To compare the NLR and host galaxy properties, we use SDSS photometry measurements to infer the host galaxy type and orientation. We adopt the position angle (`nsa_sersic_phi`), ratio of semiminor to semimajor axis (`nsa_sersic_ba`) of galaxies from the two-dimensional Sersic fit of the NASA–Sloan Atlas catalogue (Blanton et al. 2011). In order to distinguish between the discs and the elliptical galaxies in our sample, we use the fraction attributed to the r-band de Vaucouleurs component (`fracDev_r`) from the SDSS PhotoObjAll table in DR14 and the galaxy zoo fraction of votes for the disc galaxy (`P_CS`) from the Galaxy Zoo 1 data release, following the formalism in Zheng et al. (2015) and Barrera-Ballesteros et al. (2016). When the `fracDev_r` is less than 0.7 or the `P_CS` is greater than 50 per cent, this object is considered to be a disc galaxy. Among our sample of 308 AGN candidates, 225 objects are classified as discs and 60 objects are classified as ellipticals by this criterion.

3 MORPHOLOGICAL MEASUREMENTS

In this section, we describe the NLR map and our methods to identify bi-conical morphology and to quantify its position angle (Section 3.1), opening angle (Section 3.2), and concentration (Section 3.3).

3.1 Identification of bi-polar ionization cone

In Fig. 1, we show several example AGN candidates from Wylezalek et al. (2017). As shown in the left-hand panel, each spaxel is classified as either star formation dominated, composite, or AGN-dominated based on its position in the BPT diagram (Wylezalek et al. 2017). For the purpose of measuring the NLR morphology, we take only the AGN spaxels as part of the NLR. These regions

display a diverse range of morphology – disconnected blobs, bi-cone, centralized blob, ring, irregular, or some combination of the above. Our final measurements are based on an ionization bit map, in which spaxels are set to 1 if they are classified as AGN-dominated and 0 otherwise. As shown in the maps, the data are confined to a region where there is high signal-to-noise ratio (S/N). This creates an arbitrary mask on the data that has to be taken into account in the morphological measurements.

The bi-conical morphology is a strong periodic feature when expressed in polar coordinates. Specifically, because it appears twice in the 2π circle, it corresponds to the $m = 2$ mode in the azimuthal Fourier series representation of the ionization bit map. To measure the strength of this mode, we express the ionization bit map as a function of the azimuthal angle, θ , as shown in the right-hand panel of Fig. 1, and to decompose it into a Fourier series.

The S/N mask imposes a cut-off to the number of spaxels in each azimuthal angle. So, instead of counting the total number of AGN spaxels along each direction, we use the fraction of AGN spaxels, $f(\theta)$. The circle is divided into 36 bins each 10 deg wide. The AGN spaxel fraction $f(\theta)$ is calculated in each of the bins and expressed as a function of the East of North position angle θ . The origin is taken as the centre of the IFU that coincides with the photometric centre of the galaxy measured from SDSS image.

We then decompose the fraction as a function of position angle $f(\theta)$ into a Fourier series:

$$f(\theta_k) = a_0 + \sum_{m=1}^{\infty} [a_m \cos(m\theta_k) + b_m \sin(m\theta_k)], \quad (1)$$

where

$$\begin{cases} a_m = \frac{2}{2\pi} \sum_{k=1}^{36} f(\theta_k) \cos(m\theta_k) \frac{10\pi}{180} \\ = \frac{1}{18} \sum_{k=1}^{36} f(\theta_k) \cos(m\theta_k), \\ b_m = \frac{1}{18} \sum_{k=1}^{36} f(\theta_k) \sin(m\theta_k), \\ \theta_k = (10k - 5) \text{deg}; (k = 1, 2, 3, \dots, 36). \end{cases} \quad (2)$$

The $m = 0$ mode represents the circularly symmetric component and $m = 2$, the bi-polar component. We use the ratio of the amplitudes of the $m = 2$ to the $m = 0$ modes, $A_2/A_0 = \sqrt{a_2^2 + b_2^2}/a_0$, to represent the significance of the bi-polar component. The A_2/A_0 value is in the range of 0 to 1. A small value means that the morphology is close to circularly symmetric (e.g. bottom right of Fig. 1), while a large value represents a more bipolar or biconical morphology (e.g. top right of Fig. 1). We visually inspect each object and find that most objects with A_2/A_0 above 0.1 show clear bi-cone morphology, which accounts for 248 (80.5 per cent) objects among the sample. This high fraction supports that majority of the NLRs should be intrinsically bipolar.

When the $m = 2$ mode is present, we can use the phase of this Fourier mode as the position angle of the bicone, $\phi_{\text{fou}} = \arctan(b_2/a_2)/2$, shown in Fig. 1. The objects with lower values of $A_2/A_0 < 0.1$ do not exhibit bi-cone morphology and their position angle ϕ_{fou} becomes ill-defined. Hereafter, we use the ratio A_2/A_0 as a measure of the strength of the bi-conical morphology and ϕ_{fou} as its position angle.

3.2 Opening angle of ionization cone

The opening angle is an important characteristic of the bicone, which, in the unification model, is tied to the ratio of type I to type II AGN. However, with the two-dimensional NLRs map, the only observable is the projected opening angle $2\psi'$ (ψ' is the projected half opening angle) on the plane of the sky.

²<http://skyserver.sdss.org/casjobs/>

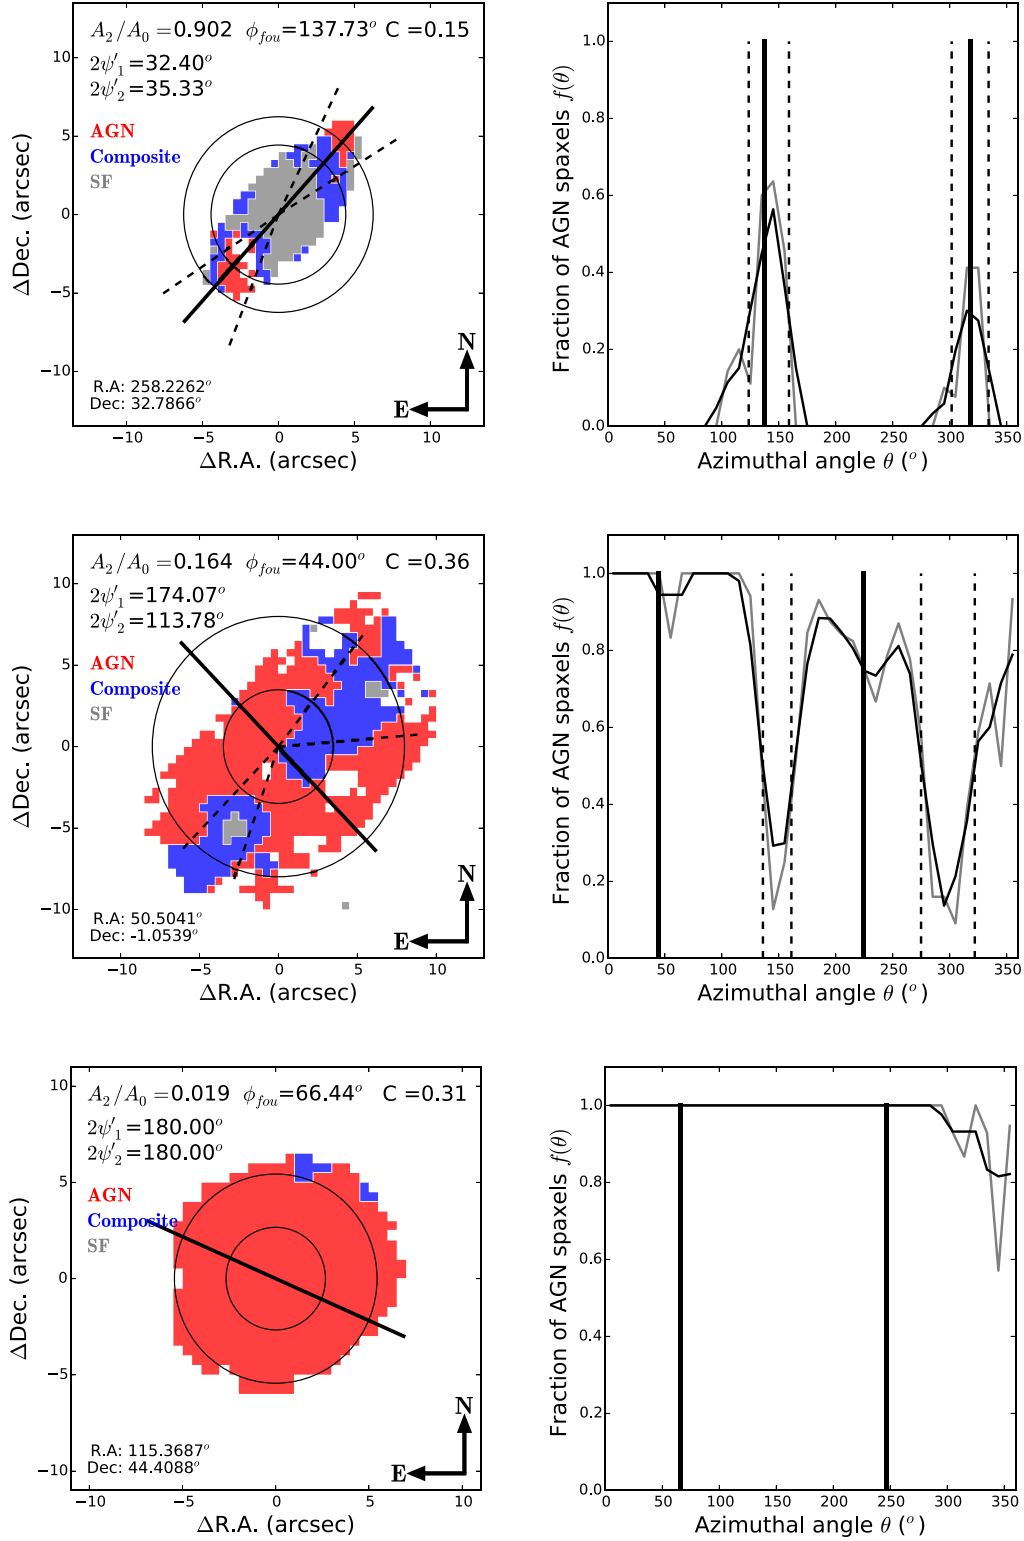

Figure 1. Examples of measuring the position angle, opening angle, and concentration. Left-hand panels are the [NII]-BPT diagrams. The grey curves in right-hand panels are the corresponding fraction of AGN spaxels along the azimuthal angle. The black curves are produced by smoothing the grey ones with a three-pixel boxcar. The position angle (black lines) is the result of our Fourier analysis. Boundaries (dashed lines) of bicone are determined by where the AGN fraction drops to half of the maximum value. A_2/A_0 is the ratio of mode $m = 2$ to $m = 0$ of the Fourier series. C is the concentration index of the emission-line region: the logarithmic ratio of the circular radius containing 80 per cent (r_{80} , black circle) of a cone's light to the radius containing 20 per cent (r_{20} , black circle) of the AGN spaxels.

When a bicone is present, the edges of the cone correspond to sudden drops in the fraction of the AGN spaxels along a certain azimuthal angle. To capture this feature, we define the cone boundary to be where the AGN fraction curve, $f(\theta)$, drops to half of its maximum value, i.e. the opening angle is the full width at half maximum (FWHM) of the fraction curve. To mitigate noise and the non-monotonic features in the curve, we smooth the angle function $f(\theta)$ with a three-pixel boxcar. If the boundaries cannot be found, the opening angle is set to 0 deg when the mean value is lower than half of the maximum value, otherwise, it is set to 180 deg. The opening angle of the bicone on each side is measured separately. Their mean is taken to be the representative projected opening angle for the AGN. The measured position angles and opening angles are in excellent agreement with the by-eye classification.

As shown in Fig. 2, there is a strong anticorrelation (Spearman correlation Test: $r = -0.55$, p -value $< 10^{-9}$, listed in Table 1) between the strength of the bicone A_2/A_0 and its opening angle. This is consistent with our expectation that when the projected opening angle becomes large, the bicone becomes less distinct and prominent.

3.3 Concentration

The inclination of the bicone also affects the radial distribution of the NLR map. When viewed pole-on, the bicones would have a centrally concentrated morphology. When the inclination angle is larger, the V-shaped morphology is less radially concentrated (Mulchaey et al. 1996b).

The concentration index C (Bershady, Jangren & Conselice 2000) was first adopted for stellar light to describe the morphology of galaxies – high-concentration values are characteristic of ellipticals and lower ones of discs. In this paper, we use it to describe the distribution of the AGN emission region. It is defined as the logarithmic ratio of the circular radius containing 80 per cent (r_{80}) of the AGN spaxels to the radius containing 20 per cent (r_{20}) of the spaxels, i.e. $C = \log_{10}(r_{80}/r_{20})$. A large concentration value indicates a majority of AGN region is concentrated at the centre. For a solid circle, $C = \log_{10}(2) \approx 0.3$. If the centre is not filled, e.g. a ring (Fig. 3), or a bicone, the value of C is smaller than 0.3. Through the visual inspection, we find that the ring-like morphology of AGN regions in nine objects having small values of C .

As shown in Fig. 2, there is a significant anticorrelation ($r = -0.3$, p -value $= 7.3 \times 10^{-8}$) between the A_2/A_0 and C index. The correlation between the opening angle and C is not significant ($r = 0.01$, p -value $= 0.87$). This indicates that systems with more prominent bicones (larger values of A_2/A_0) are less concentrated, possibly because of the high-inclination angle of the cones, consistent with our expectations.

4 RESULTS

In this section, we present our analysis and results on the intrinsic opening angle of the ionization cone (Section 4.1), the correlations between the NLR morphology and the mid-IR colour (Section 4.2), and the alignment between the NLR and the host galaxy (Section 4.3).

4.1 The intrinsic opening angle of ionization cones

A large fraction (80.5 per cent) of NLRs in type II AGN in our sample shows biconical morphology, in agreement with the predic-

Figure 2. The relationships between the A_2/A_0 , opening angle, and concentration index C . The rank correlation coefficient r and the probability of the null hypothesis (no correlation) p are indicated in every panel.

Table 1. Summary of the Spearman correlation coefficients r between the NLR morphological parameters (bi-polar prominence A_2/A_0 , the projected half opening angle ψ' , the concentration index C), infrared colour (W4–W2), and the ratio of the galaxies' semiminor to semimajor axes (b/a). The value in the bracket is the p -value.

	ψ'	C	W2–W4	b/a (discs)	b/a (ellipticals)	b/a (All)
A_2/A_0	−0.55 (9.5×10^{-26})	−0.3 (7.3×10^{-8})	0.34 (1.3×10^{-9})	−0.31 (4.2×10^{-6})	−0.31 (6.6×10^{-3})	−0.30 (1.3×10^{-7})
ψ'	–	0.01 (8.7×10^{-1})	−0.16 (8.8×10^{-3})	0.19 (1.1×10^{-2})	0.29 (3.1×10^{-2})	0.20 (1.5×10^{-3})
C	–	–	−0.42 (1.4×10^{-14})	0.03 (6.9×10^{-1})	0.06 (6.1×10^{-1})	−0.02 (7.7×10^{-1})
W2–W4	–	–	–	−0.18 (8.6×10^{-3})	−0.11 (3.3×10^{-1})	−0.12 (4.0×10^{-2})

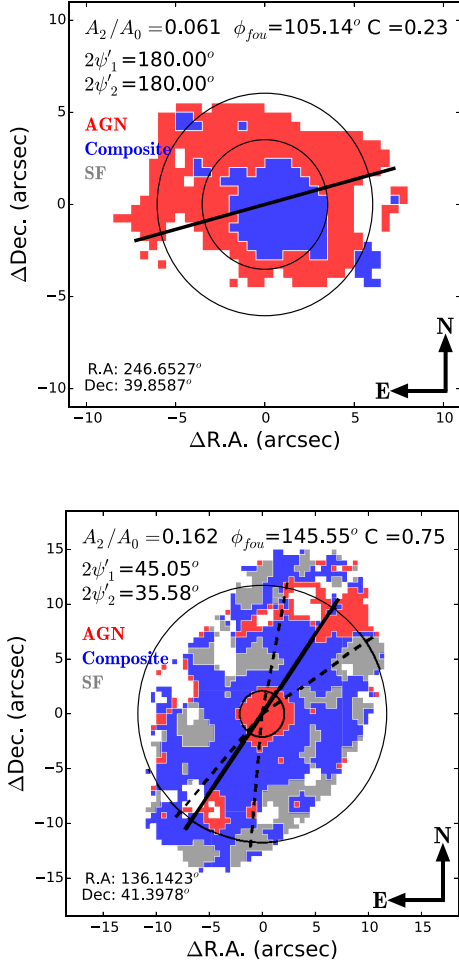

Figure 3. Upper panel: Examples of AGN with small and large concentration values.

tion of the unification model. From the distribution of the projected opening angles (Fig. 4), we can infer the distribution of the bicone intrinsic opening angles. In our analysis, we must take into account the selection effect that the MaNGA AGN sample from Wylezalek et al. (2017) contains only type II AGN. Modulo this constraint, we make an assumption that the viewing angle is random.

First, we determine the expected distribution of projected angles in the case of a single cone opening angle. For a given cone with an intrinsic half opening angle of ψ at an inclination angle of θ , the projected half opening angle ψ' can be expressed as

$$\psi' = \arctan\left(\frac{\tan \psi}{\sin \theta}\right) \dots \dots \theta > \psi, \quad (3)$$

$$\psi' = 90^\circ \dots \dots \theta \leq \psi. \quad (4)$$

Here, the inclination angle θ is the angle between the LOS and the bi-cone axis. If the inclination angle θ is smaller than ψ , i.e. the observer's LOS is inside the cone (type I AGN), then we discard the system from the predicted distribution because it would be excluded from our observed sample based on our type II AGN selection.

As an illustration, the distribution of isotropically projected opening angles of a cone with a fixed half opening angle ψ is shown as the orange line in upper left-hand panel of Fig. 4. It is narrow and peaked around the value of the intrinsic opening angle, because there is a relatively high chance of being close to edge-on ($\theta \sim 90$ deg). In fact, this distribution is much narrower than the observed distribution of the projected half opening angles ψ' that makes it clear that there has to be a range of intrinsic opening angles in order to explain the observations.

We assume that such a distribution of the intrinsic half opening angle is a smooth function that can be approximated by analytical models. To include possibilities of different dispersion and skewness in the distribution, we consider Gaussian and Beta distribution. The Gaussian $P(\psi) = G(\psi_c, \psi_\sigma)$ is a symmetric distribution parametrized by the central value ψ_c and the standard deviation ψ_σ . The Beta distribution $P(\psi) = B(\alpha, \beta)$, parametrized by α and β , is asymmetric if $\alpha \neq \beta$. The parameters are to be determined by fitting the model-predicted distribution to our data with a Markov chain Monte Carlo (MCMC) procedure described in the following:

Given an intrinsic half opening angle distribution $P(\psi) = G(\psi_c, \psi_\sigma)$ or $P(\psi) = B(\alpha, \beta)$, we predict the projected opening angle distribution $P(\psi')$ with a Monte Carlo simulation:

1. We draw 200 intrinsic opening angles ψ from the Gaussian distribution $G(\psi_c, \psi_\sigma)$ or $B(\alpha, \beta)$.
2. For each of the intrinsic opening angle ψ , we project it, according to equation (3), with 500 realizations of random isotropic inclination angles $P(\theta) \propto \cos(\theta)$.
3. We compile the distribution of $200 \times 500 = 100\,000$ projected opening angles, discard the ones corresponding to type I AGN ($\theta < \psi$) and then normalize the distribution.

We then fit this predicted opening angle distribution to the data using an MCMC package (emcee, <http://dfm.io/emcee/current/user/line>). The likelihood is evaluated for each data point, i.e. each opening angle bin of 10° , based on an assumed Gaussian likelihood function. The total likelihood is a product of all the likelihoods in all the bins. We adopt flat priors on the parameters and run 10^5 steps in the Markov chain.

The bin with the largest projected opening angle $2\psi' = 180$ is excluded in the fit, which accounts for a small fraction of the sample (12 per cent, 38/308). Systems in this bin correspond to halo-like emission-line regions with no clear bicones. In unification model, these systems should correspond to type I AGN and would not be

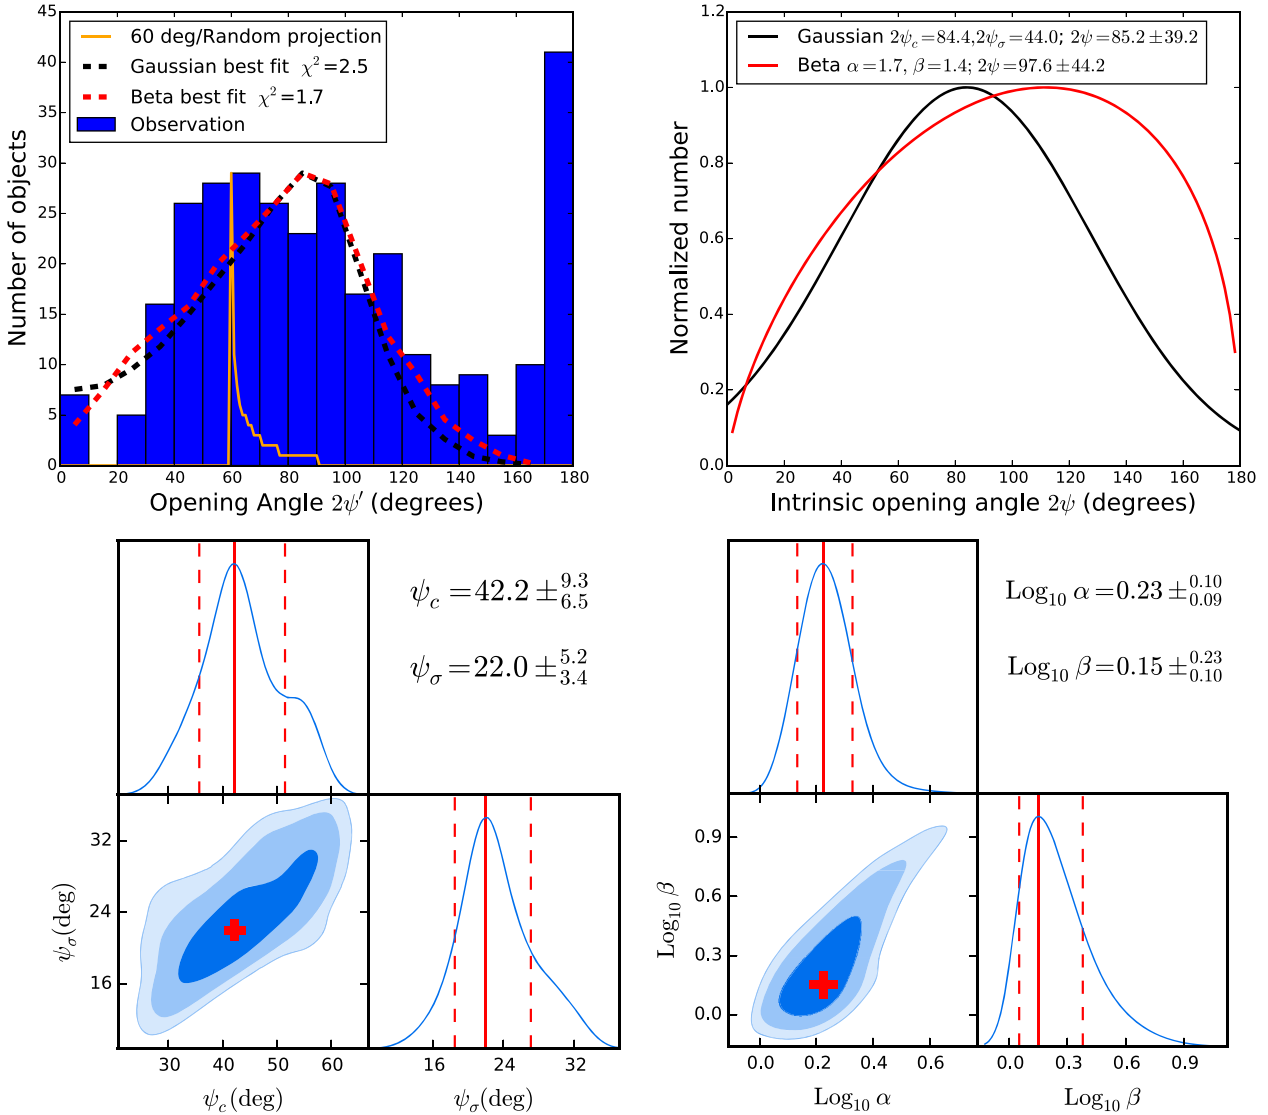

Figure 4. The MCMC result of the distribution of opening angles. We assume a Gaussian and a Beta distribution of the intrinsic angle projected randomly and isotropically on to the plane of the sky. Upper left: The data and best-fitting model. The vertical red solid line represents the peak value of the intrinsic angle. Upper right: the best-fitting intrinsic angle of Gaussian and Beta function. Lower panel: the posterior on the Gaussian $G(\psi_c, \psi_\sigma)$ and Beta $B(\alpha, \beta)$ parameters of the intrinsic half opening angle distribution. The red cross marks the best-fitting value of the parameters. The red solid (dashed) lines represent the peaks (1σ error) of the parameters.

selected in our sample. But it is possible that beam smearing limits our ability to resolve bicones in some cases. Alternatively, the dust geometry in these cases may be more complex than assumed in the dusty torus model. Either way, these cases account for a small fraction of the sample. In our analysis, they are excluded in the modelling.

By construction, there is not much constraining power on the population of AGN with the largest opening angles. This is because such systems are most likely observed as type I AGN and would contribute little to the type II AGN population even if they are abundant. On the other hand, the population with small opening angles should be relatively well constrained. The number of AGN with small projected opening angle is relatively small in our data. So, although there are uncertainties on the projected opening angles at the 10° – 20° level due to the finite bin size and smoothing, etc.,

such that the number count in each bin may not be exact, our data imply that there is no significant population of AGN with small intrinsic cone opening angles.

The posterior distribution of the Gaussian parameters (ψ_c, ψ_σ) and Beta parameters (α, β) is shown in Fig. 4. For the Gaussian function, the best-fitting values (peak of the posterior distribution) and the errors (68 per cent credible interval) of the peak half opening angle and the standard deviation are $\psi_c = 42.2^{+9.3}_{-6.8}$ deg and $\psi_\sigma = 22.0^{+5.2}_{-3.4}$ deg, respectively. For the Beta function, the best-fitting values (peak of the posterior distribution) and the errors (68 per cent credible interval) are $\log_{10} \alpha = 0.23^{+0.10}_{-0.09}$ and $\log_{10} \beta = 0.15^{+0.23}_{-0.10}$, respectively. The peak of the intrinsic opening angle and its standard deviation is $2\psi = 84.4 \pm 44.0$ deg for Gaussian function and $2\psi = 97.6 \pm 44.2$ deg for the Beta function. These fits reasonably capture the peak and the spread of projected opening angles, but

there is some small excess and deficit at angles that is not captured in the model, possibly indicating that the intrinsic distribution $P(\psi)$ differs from the assumed ones.

The best-fitting Gaussian and Beta functions are consistent at small intrinsic opening angles but deviate at larger angles. This highlights the lack of constraining power in those regimes in the sense that a dramatic increase in the population with large opening angles would not change the observables significantly due to our selection. This uncertainty would result in uncertainties in the constrained type ratio. The Gaussian and Beta functions give different type II fractions. For the Gaussian distribution, the type II fractions is ≈ 70 per cent, corresponding to a number ratio between type I and type II AGN of $\approx 1:2.3$. For the Beta distribution, the type II fractions is ≈ 61 per cent, corresponding to a number ratio between type I and type II AGN of $\approx 1:1.6$. This is calculated by averaging the type II fraction $\langle \cos \psi \rangle$ with 1000 000 realizations of ψ drawn from the best-fitting Gaussian and Beta distributions $P(\psi)$. Its implication and comparison with the literature are discussed in Section 5.1.

4.2 Correlation between NLR morphology and mid-IR colour of dusty torus

As discussed in the Introduction, a correlation between the NLR morphology and the mid-IR colour of AGN is expected because both of them depend on the inclination angle of the system under the framework of the unification model. When the observer views the dusty torus from the edge, the mid-IR emission should be redder (high W2–W4) than in the face-on case due to the colder effective dust temperature of the outer parts of the torus, as predicted by various (clumpy or smooth) torus models. At the same time, the NLR should be seen as prominent bicones (high A_2/A_0), with smallest opening angle (low $2\psi'$), and low concentration (low C).

The correlations between the mid-IR colour and the NLR morphological parameters (A_2/A_0 , $2\psi'$, and C) are shown in Fig. 5. All three of these relations have statistically significant correlations in a sense that they are all consistent with the expectations based on the unification model laid out above. The correlations of W2–W4 with the bicone strength A_2/A_0 (Pearson's $r = 0.34$, p -value = 1.3×10^{-9}) and the concentration C ($r = -0.42$, p -value $< 10^{-9}$) are stronger than the one with the opening angle $2\psi'$ ($r = -0.16$, p -value = 8.8×10^{-3}). The mid-IR colours used here are based on original fluxes without subtracting the stellar continuum. Adopting the stellar continuum subtracted fluxes does not change the results significantly (see Section 2.2). So, we only present the results with no corrections. Our result is consistent with Rose et al. (2015), who found that a larger AGN inclination angle corresponds to a redder W2–W4 colour.

The existence of these correlations suggests that the morphology of the NLR on kpc scale is connected to the dusty structure in the AGN vicinity on pc scales. The implications of these correlations are discussed in Section 5.

4.3 Alignment between narrow-line region and host galaxy

In the previous section, we have found evidence suggesting that the shape of the NLR may be linked to the mid-IR emitting dusty structure on pc scales, in agreement with the unification model. But dust on larger scales, for example in the galactic disc, may also obscure the ionizing radiation and contributes to shaping the NLR, in that case we may expect correlations between the orientation of the ionization cones and the galaxy (Lacy et al. 2007). In this section,

we investigate the links between the NLRs and their host galaxies by correlating their position angles and comparing their morphological parameters.

First, we look into the alignment between the NLR and the host galaxy in the plane of the sky. The position angle of the ionization cone is determined with Fourier decomposition of the NLR map (Section 3.1), and that of the host galaxy is from NASA–Sloan Atlas catalogue (Section 2.3). To determine their relative orientation, we measure the acute angle between the two position angles. As shown in Fig. 6, most of the acute angles between the bicones and the galaxies are closer to 90 deg, i.e. the cones are preferentially perpendicular to the major axis of the galaxy.

To test the significance of the alignment, we compare the distribution of the acute angles with a uniform distribution, which would be the case if there were no alignment between the two components. The Kolmogorov–Smirnov test gives a statistically significant result ($r = 0.19$, p -value $< 10^{-9}$ for the whole sample, $r = 0.22$, p -value $< 10^{-9}$ for discs), ruling out the case of random alignment. In addition, we divide the sample into two groups – ones with acute angle larger than 45 deg (more perpendicular) and another smaller than 45 deg (more parallel). For the whole sample, 202 of 308 angles are larger than 45 deg. There are 154 of 225 (68.4 per cent) and 34 of 60 (56.7 per cent) angles larger than 45 deg for the subsample of discs and ellipticals, respectively. The probability of $P(> 45^\circ)$ is significantly higher than 0.5 for the whole sample and discs (binomial test, p -value = 4.9×10^{-8} and 3.2×10^{-8} for the whole sample and discs, respectively). These results indicate that the polar axis of the ionization cones and the major axis of the galaxies discs are preferentially perpendicular to each other.

Secondly, additional tests can be conducted based on the inclination angles of the ionization cones, the dusty torus, and the galaxy. The galaxy's inclination is better defined with disc galaxies, for which the ratio between the semiminor to semimajor axis (b/a) has been used as a proxy of inclination. We use the parameter `nsa_sersic_ba` from NASA–Sloan Atlas catalogue (Section 2.3) and expect this ratio to be lower when the galaxy is more inclined. For elliptical galaxies, although such a ratio is also measured, it is less clear what it means for the galaxy's orientation. Based on the unification model as discussed in Section 3, there are three morphological parameters of NLR that should be correlated with the inclination of the cones – the strength of the bicone A_2/A_0 , the opening angle $2\psi'$, and the concentration C . The first one increases and the latter two decrease with the inclination angle. For the dusty torus, its inclination is expected to be positively correlated with the mid-IR colour W2–W4.

Fig. 7 shows the relations between the galaxy's semiminor to semimajor ratio and the other inclination proxies. Their correlation coefficients are calculated based on the disc galaxies, elliptical galaxies, and the entire sample, respectively. We find that, based on the whole sample, the ratio of galaxy's semiminor to semimajor axis (b/a) is significantly anticorrelated with the prominence of the ionization cone A_2/A_0 ($r = -0.3$, p -value = 1.3×10^{-7}), in agreement with our expectation that both depend on the inclination angle. The correlations between b/a and the other parameters – the cones' opening angle $2\psi'$, concentration C , and the W2–W4 colour – are not significant.

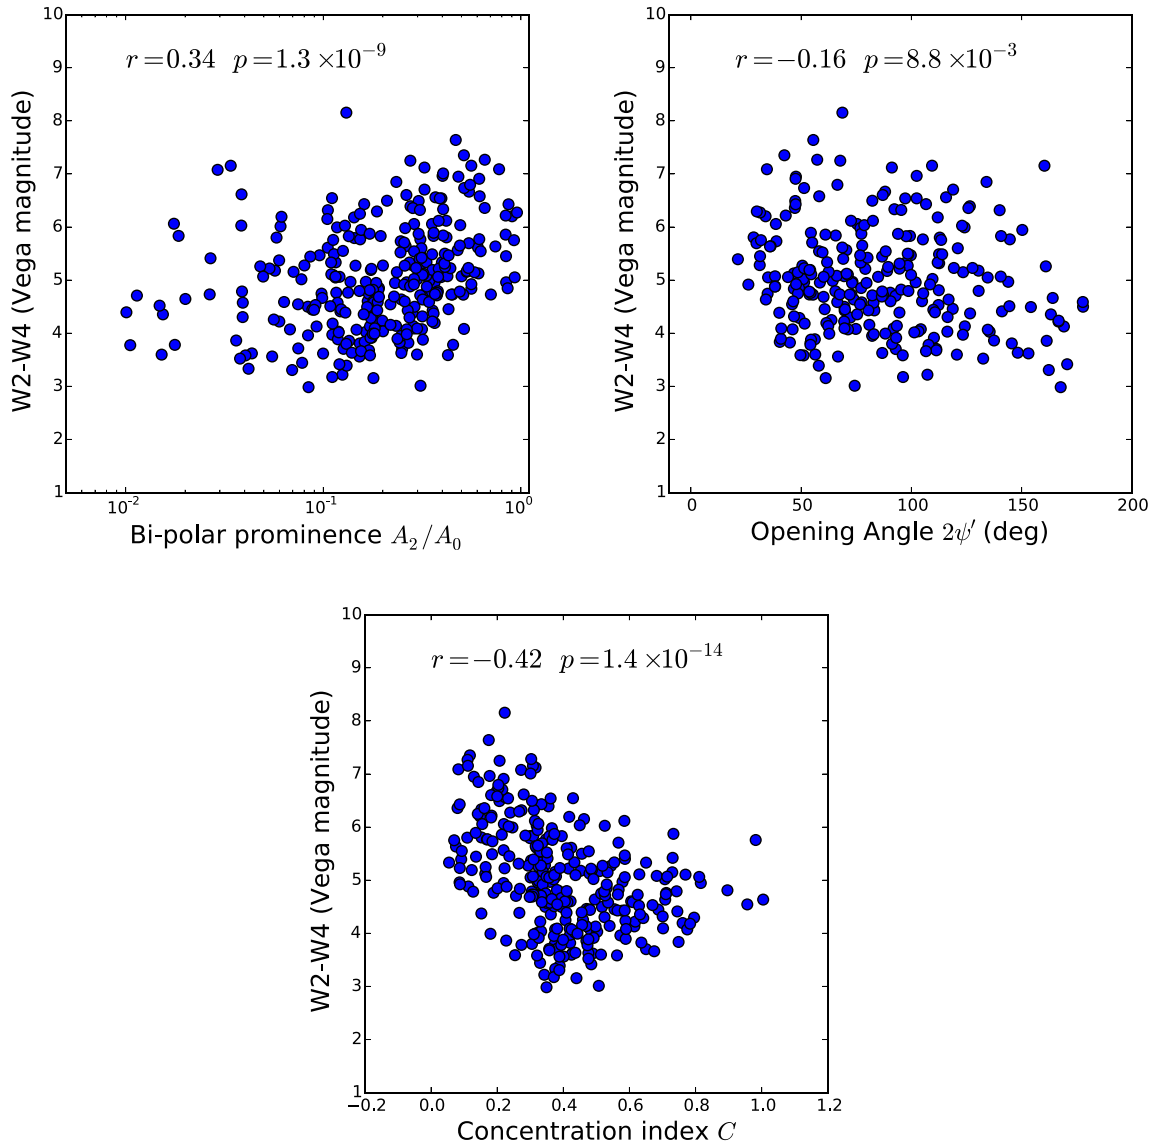

Figure 5. Infrared colour (W4–W2) versus the parameters of morphology of AGN ionization region A_2/A_0 , opening angle, and concentration index C . The rank correlation coefficient r and the probability of the null hypothesis p are indicated in every panel.

5 DISCUSSION

5.1 Tests of unification model – type I / type II ratio

In the unification model, the opening angle of the ionization cones determines the number ratio between type I and type II AGN. As a test to the unification model, we compare our results to direct demographic studies of the type ratio.

The opening angle measurements in our sample indicate a type II fraction of ~ 60 – 70 per cent at luminosities of $L_{[\text{O III}]} = 10^{39.3} - 10^{41}$ erg s^{-1} . Radio and mid-IR selected samples give type II fraction ~ 50 – 60 per cent that does not depend strongly on the AGN luminosity across a large range of luminosities $L_{\text{bol}} = 10^{43-47}$ erg s^{-1} (Lawrence & Elvis 2010, and references therein). Optically selected samples from SDSS suggest that the type II fraction decreases with the $[\text{O III}] \lambda 5007$ luminosity (Hao et al. 2005; Simpson 2005). For low luminosities AGN comparable to our sample ($L_{[\text{O III}]} \sim 10^{40-41}$ erg s^{-1}), Simpson (2005) found that the type II fraction is around 80–90 per cent, which is higher than what we

find here. At high luminosities ($L_{[\text{O III}]} \sim 10^{42-43}$ erg s^{-1}), Simpson (2005) and Reyes et al. (2008) find a lower type II ratio of 50–70 per cent. In X-ray selected samples, the optically defined type II AGN fraction is ~ 60 – 90 per cent in the low-luminosity range of $L_{2-10\text{keV}} = 10^{42.5-43.5}$ that is comparable to our sample (Merloni et al. 2014).

Although there are discrepancies in the type II AGN fraction on the order of 10–20 per cent between our results and other studies, variation of this level is seen among different demographic studies. These variations are likely due to the selection biases associated with different AGN selection methods, different redshift coverage, and different classification criteria for type I versus type II AGN. We conclude that our results are broadly in agreement with demographic studies, and there is no strong evidence conflicting with the unification model.

With *Hubble Space Telescope* (HST) imaging, Obied et al. (2016) constrain the intrinsic half opening angle of the AGN scattered light cone to be $27^\circ \pm 9^\circ$ (mean and standard deviation) among luminous

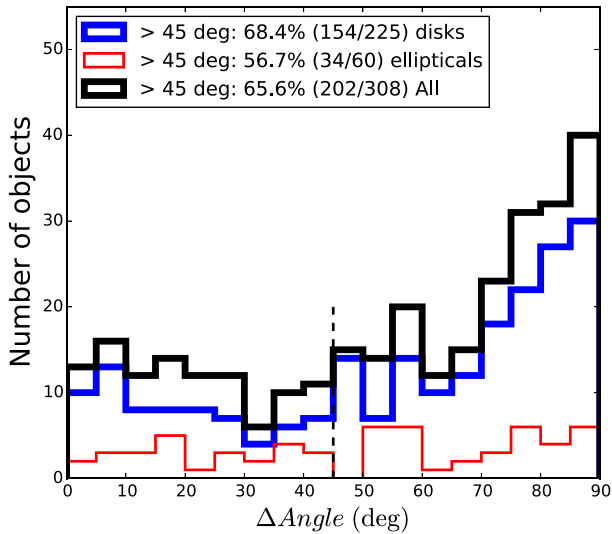

Figure 6. Distribution of acute angles between the polar axis bicone and major axis of galaxies disc. Most of the value is close to 90° which means the polar axis of bicone and major axis of galaxies disc are in the same direction. For the whole sample, 202 of 308 angles are larger than 45° . There are 154 of 225 and 34 of 60 angles larger than 45° for the sub-sample of discs and ellipticals, respectively. The probability $P(> 45^\circ)$ is significant (binomial test, p -value = 4.9×10^{-8} and 3.2×10^{-8} for the whole sample and discs, respectively) and different from $P(> 45^\circ) = 0.5$. There is also a significant difference between acute angles distribution and the uniform distribution (Kolmogorov–Smirnov test, p -value $< 10^{-9}$ for the whole sample, p -value $< 10^{-9}$ for discs). The dashed-vertical line marks the location of 45° .

type II AGN, which is smaller than our result implying a higher type II fraction. It is unclear what causes the discrepancy between Obied et al. (2016) and our result. Obied et al. (2016) point out that their results are inconsistent with demographic AGN-type ratios at comparable luminosity and redshift range and speculate that the type I fraction could be increased by allowing illuminating light to escape through a porous torus. We do not see strong evidence for such component in our sample.

The intrinsic opening angle and the type I/type II ratio inferred in our study are subject to a few sources of uncertainties. First of all, the discrete binning along the azimuthal angle and less-distinct cone boundaries introduces uncertainties of the order $\sim 10^\circ$ in the measured projected opening angle, corresponding to 10 per cent uncertainty in the type II fraction. Secondly, the morphology of the NLRs may also be affected by factors in the host galaxy, including the gas distribution, dust extinction, or contamination of the emission lines from star-forming regions, although these uncertainties are harder to quantify. Thirdly, given the observed projected opening angles, the inferred ratio also depends on the assumed function form of the intrinsic opening angle distribution. Our assumed Gaussian and Beta profiles provide satisfactory fit to the data. But in the extreme case, if there is a missing population of AGN with no obscuration at all, such a population can lower the type II AGN fraction but would not be reflected in our results. In another extreme, we would miss the completely enshrouded AGN that do not have photoionized emission-line regions.

In addition, there is a small fraction (12 per cent, 38/308) of our type II AGN sample showing halo-like NLR morphology that is rather surprising because such a morphology is expected in type I AGN in the unification model. This may be because the cones exist

but they are just too small to be spatially resolved. Or alternatively, this may indicate a dust configuration more complex than the torus model. We may indeed be looking into the ionization cone, but the direct LOS to the nucleus is blocked by individual clouds within the cone. In this case, the correspondence between the cone opening angle and the type ratio would be more complicated.

5.2 Tests of Unification Model – Source of Obscuration

The AGN photoionized emission regions reflect the illumination geometry, which in turn is shaped by the obscuration. Previous studies suggest that dust on either circumnuclear or galactic scales can obscure the AGN radiation, (e.g. Lacy et al. 2007).

Indeed, we see some evidence in favour of the obscuration occurring on circumnuclear scales. We see that as the cones become narrower or the prominence of the cone A_2/A becomes larger, the IR colours become redder. The $L_{[\text{O III}]}$ for all objects in our sample are $\sim 10^{39.3} - 10^{41} \text{ erg s}^{-1}$. Applying the relationship between $L_{[\text{O III}]}$ and L_{bol} for type II AGN (Liu et al. 2009), we find the typical L_{bol} to be $10^{42.4} - 10^{44.1} \text{ erg s}^{-1}$. Adopting the calculation (Barvainis & Richard 1987; Elsner, Shibazaki & Weisskopf 1987; Jiang et al. 2017), the IR emission at W2–W4 band (4.6–22) is produced on the scale. Therefore, if there is a relationship between photoionized regions and the warm IR, the obscuration and the illumination must be established on these small scales.

In this work, we find that the higher concentration of the AGN NLR emission corresponds to hotter dust, consistent with the expectation that type I AGN or AGN with small inclination have higher NLR concentration (Mulchaey et al. 1996a; Schmitt et al. 2003). In addition, Schmitt et al. (2003) did not find type I to have smaller NLR than type II, but they have compared their morphology: The morphology of ionized regions of Seyfert I are more round shaped and that of Seyfert II are more cone like. These findings, together with ours, all suggest that the apparent concentration of the NLR is largely determined by the inclination angle.

We also see that the orientation of the AGN ionization cones is related to the position angle (major axis) of the galaxy. In disc galaxies, the ratio of galaxy’s semiminor to semimajor axis (b/a) is significantly anticorrelated with the prominence of the ionization cone A_2/A_0 . Our measurements show that the ionization region cones are preferentially orthogonal to the major axis of the galaxy. This could be because the orientation of the obscuring material is correlated with the orientation of the galaxy disc. Despite a vast difference of physical scales, there are some theoretical models of AGN activity in which there is a relationship between the accretion disc and the galactic disc (Shlosman, Frank & Begelman 1989; Hopkins & Quataert 2009, 2010). Given the fuelling of galactic gas on to the AGN in these models, one may expect a certain degree of alignment between the AGN obscuration and the host galaxy disc. However, Pjanka et al. (2017) find no evidence for megamaser discs preferentially aligning with the galactic discs casting doubt on the physical connection between AGN obscuration and the galactic orientation. Alternatively, the correlation between the NLR and disc orientation could have something to do with the extinction: In the disc, we would have trouble seeing photoionized gas beyond a distance of kiloparsecs (Lacy et al. 2007). From our evidence of the connections between ionization cone, IR colour, and the galaxy disc, we conclude that both circumnuclear obscuration and the host galaxy disc play a part in the morphology of AGN NLRs.

A subset of our AGN show ring-like morphologies of the NLR with a hole in the centre (top panel of Fig. 3). This morphology is not well captured by the unification model. One possible explanation

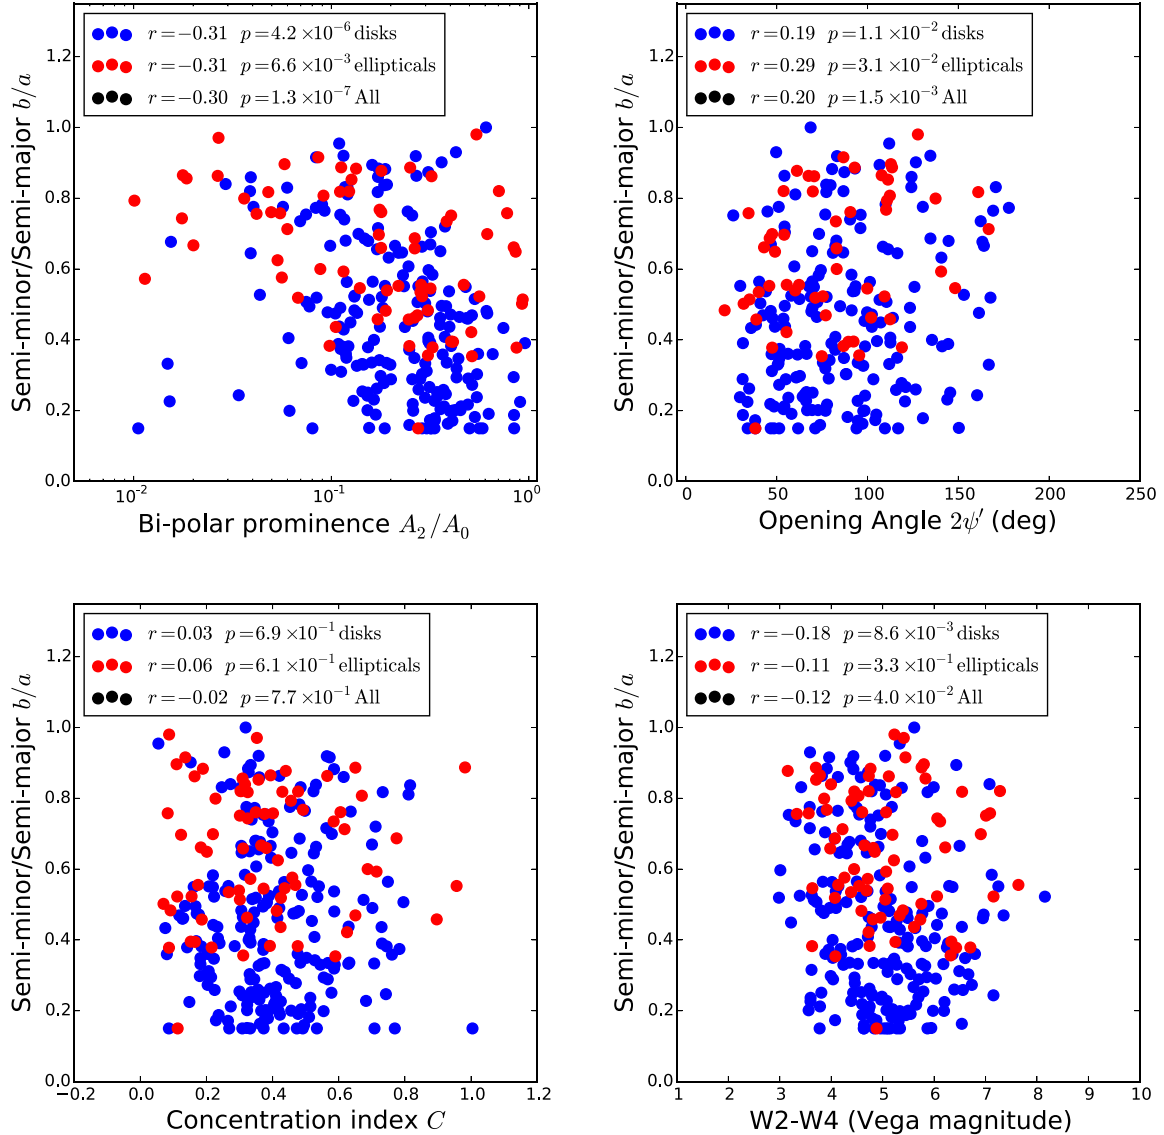

Figure 7. The ratio of semiminor to major axis of the galaxy versus the parameters of morphology of AGN ionization region A_2/A_0 , opening angle, concentration index C , and the infrared colour (W4–W2). The red points represent the ellipticals, while the blue ones represent the disc galaxies. The rank correlation coefficient r and the probability of the null hypothesis p are indicated in every panel.

is that the central engine is in a period of inactivity at a small inclination angle. Another possible explanation is that the central engine is obscured by a dusty cloud or dominated by a nuclear star-forming region.

6 CONCLUSIONS

The geometry of the AGN obscuration remains an active topic in the discussion of AGN unification model. In this paper, we approach this question with statistical studies of the NLR morphology. Our sample consists of 308 type II AGN candidates selected from the MaNGA IFU survey (Wylezalek et al. 2017), which offer spatially resolved two-dimensional NLR maps.

To identify the bi-conical shape of the ionized region, we decompose the azimuthal dependence of the NLR maps into Fourier series. We find that the power of the $m = 2$ mode (A_2/A_0) signals the presence of the bicones. The phase of the $m = 2$ mode corresponds to the position angle of the cones. The opening angles of the cones

are characterized by the FWHM of the NLR azimuthal profile. 81 percent of the AGN are found to have bi-conical or bi-polar NLRs. The results of automated morphological measurements are robust and are in good agreement with visual inspection.

We use the distribution of the measured opening angles to infer the intrinsic opening angles of the ionization cones assuming random projection. We find that the data are inconsistent with a single intrinsic opening angle. To account for the spread, we model the distribution of the intrinsic opening angle with a Gaussian and a Beta function. With MCMC fitting, we constrain the mean and the standard deviation of the intrinsic opening angles in our sample to be 85.2–97.6 and 39.2–44.2 deg. Our result suggests that the number ratio of type I and type II AGN should be ≈ 1 : 1.6–2.3, or a type II AGN fraction of 60–70 per cent that is consistent with the observed number ratios of type I to type II at low luminosities.

We find that the NLR morphological parameters, i.e. bicone strength A_2/A_0 , opening angle, and concentration index, are significantly correlated with the *WISE* mid-IR colour W2–W4, which

reflects the circumnuclear dust geometry. The correlation coefficients between W2 and W4 colours and the morphological parameters are $r = 0.35$, p -value $\sim 10^{-9}$, $r = -0.42$, p -value $< 10^{-9}$, $r = -0.16$, and p -value $= 8.4 \times 10^{-3}$, respectively, for the bicone strength, opening angle, and concentration index. This indicates that AGN with redder mid-IR colours (lower temperature of dust or more edge-on dusty torus) correspond to a more prominent, narrower, and less centrally concentrated bicone morphology. These results are in agreement with the expectations that the orientation of ionization cones is related to that of the toroidal circumnuclear dusty structure.

Furthermore, we find significant evidence (binomial test, p -value $= 4.9 \times 10^{-8}$) that the major axis of the galaxy disc and the AGN ionization cones is preferentially orthogonal to each other. In addition, we find correlations between indicators of galaxies' and ionization cones' inclinations. The ratios of the galaxies' semiminor to semimajor axis (b/a) are anticorrelated with the prominence of the ionization cones A_2/A_0 and positively correlated with the cone opening angles. These relationships between NLRs and the host galaxies could arise when the orientation of the obscuring material is correlated with the orientation of the galaxy disc. Alternatively, this could be due to galactic disc extinction contributing to shaping the ionizing radiation or that the emission lines are obscured on galactic scales.

It has long been debated whether AGN obscuration is due to circumnuclear material, to the galactic disc, or both. We find evidence for both processes in our study. In future studies of AGN demographics, it will be important to quantify the relative importance of these two contributions as a function of AGN luminosity and host galaxy types.
