AGRADECIMENTOS

Eis que me sento novamente para escrever em agradecimento à muitas pessoas que tornaram esse trabalho possível; e finalizar outro ciclo marcante em minha vida.

Primeiramente agradecer aos meus orientadores, Maria de Fátima Bitencourt e Jiří Konopásek pelos valiosos ensinamentos durante esses quatro anos. Há ainda muito a aprender, mas sei que posso me espelhar em vocês. Obrigado por me acolher tão bem no seu grupo, Fátima. Jiří thank you very much for all your patience and teachings, and also for the amazing fieldtrips here in South America.

Agradeço aos membros da banca avaliadora por disponibilizar seu tempo e entusiasmo para avaliar e discutir essa tese. Dra. Brenda Chung da Rocha, Dra. Cristine Lenz e Dr. Sebastián Oriolo, muito obrigado!

Agradeço também a todos os meus coautores pelas discussões, e pelas coisas que me ensinaram durante o desenvolvimento dos artigos. Agradeço as agências de fomento CAPES e CNPq por investirem e acreditarem na nossa pesquisa, principalmente através do projeto Capes-Diku (CAPES 88881.117872/2016-01, 88887.141226/2017-00/ UTF-2018-10004). Agradeço a UFRGS e ao seu ensino público superior de extrema qualidade pela oportunidade de estudar e representar essa escola.

A minha irmã de sangue, Charline, e aos meus irmãos de coração, Junior, Maurício e Thaize, que sempre me apoiaram, obrigado. Obrigado também por aumentarem a nossa família, com a chegada dos nossos pequenos Matteo, Lucca, Bella, Nina e Benjamin (que antes de nos darmos conta serão tão grandes quanto nós). Ana, Rafa e Alexandre, meus irmãos por “tabela” (haha), obrigado! É muito bom compartilhar momentos com todos vocês.

Meus pais, meus heróis, meus grandes amores, nada disso seria possível sem vocês; mãe, pai, obrigado por tudo que me ensinaram! Meus avós, dedico essa tese a vocês, que mesmo sem ter tido a oportunidade estudar muito (ou mesmo de aprender a ler), sempre acreditaram em mim; sinto que esse sonho também é de vocês. Aos meus primos Rodrigo, Cawan, Ruan obrigado pelos momentos de diversão; é sempre importante sorrir em momentos tão difíceis que passamos durante dois anos de pandemia. Ao meu amigo João Augusto, por me mostrar que a vida é simples, obrigado!

Aos meus amigos Pedro, Cícero e Alejandro, que além de amigos, dividiram estadia comigo durante os tempos de doutorado. Ficar em casa na pandemia foi um

pouco mais fácil devido as nossas conversas sobre assuntos aleatórios e aos nossos churrascos sem convidados. Aos amigos que a geologia me proporcionou, que embora poucos nos vemos, sempre é um encontro especial, Thaili, Guilherme, Fernando, Ingrid, Marciéli, Gessé, Alex, Rauflin, Douglas. Obrigado também a turma de *Beverly Hills*: Renato, Christian, Gean, Pedro, Rafael e Erik... bora marcar uma janta? só decidir “que horas mais ou menos”.

Ao maravilhoso grupo do Magmatismo Sintectônico: uma família muito unida e as vezes um pouco agitada (mas é um agitado de se amar). Dioni, Steh, Pedrinho, Gepeto, Amós, Camila T., Cris, Diegão, Duda, Felipe, Fran, Paulista, Victor, João, Pezzat, Thay, Elisa, Camila S., obrigado a todos vocês pelos almoços do RU, pelas discussões engrandecedoras de geologia e da vida, pelos cafés pós-almoço com memes e besteiras. Obrigado por todos os campos, sempre uma honra estar ao lado de vocês nessas experiências.

Aos meus amigos que conheci (e “re-conheci”) na viagem mais linda de minha vida; cada paisagem, cada momento, foi tudo tão mágico! Obrigado também por embalarem madrugada a fora muitas conversas de *whatsapp* durante a pandemia. Os Andes são tão lindos, que combinam perfeitamente com o espetáculo de pessoas que vocês são! Obrigado pelos momentos únicos durante a viagem, obrigado por poder descontrair com vocês várias vezes, o que foi sem dúvida de suma importância para que hoje eu pudesse estar aqui escrevendo essa tese e esses agradecimentos. Amanda, Bibiana, Brenda, Dionatan, Fernanda, Mariane, Ricardo, Rhoana, muito obrigado! Obrigado duplo para a Amanda que revisou o texto da tese!

To the Tromsø crew: Jack Percival, Paul Heckmann and Petar Pongrac, thank you very much for the great times we spent together in Norway. That was the most amazing experience of my entire life! Hope we can meet again soon to the traditional Friday beer.

Ao elenco multimilionário do Battisti F.C., aquele abraço. Se a gente jogasse um pouco melhor, talvez nem precisaria escrever essa tese (hahaha).

Aos leitores, espero que possam desfrutar do conteúdo disposto aqui e agradeço por seu tempo. A vida é sobretudo uma questão de tempo... de meu tempo dedicado a apresentar a vocês o melhor texto que eu poderia escrever com o tempo e conhecimento que hoje possuo; e de seu tempo, em ler atentamente, inclusive essa frase. O conhecimento conecta, e o que eu pude aprender escrevendo essa tese, espero que também vos seja útil.

Obrigado à natureza, a única e eterna expressão de perfeição!

Perdoem-me se esqueci de alguém; mas não se preocupem, vocês estão em minha memória, e são, com toda certeza, muito mais que apenas nomes em um pedaço de papel!

RESUMO

A estratigrafia original de bacias pré-colisionais é em geral bastante modificada durante as colisões devido aos diversos processos orogênicos, incluindo a intensa deformação. O Cinturão Dom Feliciano, localizado no sul do Brasil e Uruguai, é parte de um extenso sistema orogênico neoproterozoico e teve sua estruturação principal desenvolvida por deformação prolongada do final do Criogeniano ao Ediacarano. Portanto, a reconstrução de sua evolução geológica e de suas bacias sedimentares originais é bastante dificultada. Esta tese busca avaliar a história pré-colisional e colisional do setor central do Cinturão Dom Feliciano com base no estudo da relação espacial e temporal dos complexos Porongos, Várzea do Capivarita e Passo Feio. A história pré-colisional do cinturão foi investigada através do estudo geocronológico e de isótopos de oxigênio em cristais de zircão de rochas metavulcânicas intercaladas com as sequências metassedimentares dos complexos Várzea do Capivarita e Porongos. Os resultados trouxeram robustas evidências de uma conexão pré-colisional, em ca. 800–770 Ma, entre as rochas do antepaís e do além-país do Cinturão Dom Feliciano. A história colisional do cinturão foi investigada através do estudo de amostras metassedimentares dos complexos Porongos e Passo Feio por meio de modelamento das condições P–T, determinações geocronológicas de Lu–Hf granada-rocha total e de U–Pb *SIMS* em monazita. Os novos dados permitem estabelecer dois períodos distintos de espessamento crustal, o primeiro em ca. 660 Ma e o segundo em ca. 565 Ma e, por consequência, trazem evidências de migração para oeste da frente orogênica em um sistema orogênico transpressivo de longa duração. Os ambientes sedimentares originais e suas relações foram também investigados por meio de dados geoquímicos e isotópicos (Sr-Nd) compilados da literatura para amostras metavulcânicas intercaladas com metassedimentos dos três complexos estudados. Estes dados, em conjunto com novos dados geoquímicos, de Sr-Nd e de U-Pb em zircão obtidos para os complexos Passo Feio e Porongos, sugerem pela primeira vez um magmatismo compartilhado entre o Complexo Passo Feio e a sequência Capané do Complexo Porongos em ca. 600–580 Ma. Tais dados também corroboram um magmatismo compartilhado em ca. 810–770 Ma entre o Complexo Várzea do Capivarita e a sequência Cerro da Árvore do Complexo Porongos.

Palavras-chave: *bacias pré-colisionais; rochas metavulcânicas; espessamento crustal; sistema orogênico transpressivo; Cinturão Dom Feliciano.*

ABSTRACT

The original stratigraphy of pre-collisional basins is difficult to reconstruct due to the subsequent mountain-building processes, including extensive deformation. The Dom Feliciano Belt, situated in southern Brazil and Uruguay, is part of an extensive Neoproterozoic orogenic system which had its main structure developed by protracted deformation from the Cryogenian to the Ediacaran. Therefore, reconstructing its evolution and the stratigraphy of its original basins is arduous. The present thesis aims at evaluating the pre-collisional to collisional history of the Dom Feliciano Belt central sector, based on the spatial-temporal relationships of the Porongos, Várzea do Capivarita and Passo Feio complexes. The orogen pre-collisional history was investigated through geochronological and oxygen isotope studies in zircon from metavolcanic rocks interbedded with the metasedimentary sequences of the Várzea do Capivarita and Porongos complexes. The results provide strong evidence of a pre-collisional relationship, at ca. 800–770 Ma, between the Dom Feliciano Belt foreland and hinterland rocks. The collisional history of the belt was investigated through P–T petrogenetic modelling, Lu-Hf garnet-whole-rock and U–Pb SIMS monazite dating performed in metasedimentary samples from the Porongos and Passo Feio complexes. The obtained data establish two distinct periods of crustal thickening, the first at ca. 660 Ma and the second at ca. 565 Ma. Evidence points to an orogenic front migration towards the west in a long-lived transpressive orogenic system. The original sedimentary environments and the relationship of the three studied complexes were also investigated through geochemical and isotopic (Sr-Nd) data compiled from the literature for metavolcanic samples interbedded with their metasediments. The literature dataset combined with new geochemical, Sr-Nd and U-Pb data obtained for the Passo Feio and Porongos complexes leads to the novel conclusion of a shared tectonic evolution between the Passo Feio Complex and the Porongos Complex (Capané sequence) at ca. 600–580 Ma. Such data also corroborate the presence of a shared magmatism at ca. 810–770 Ma between the Várzea do Capivarita Complex and the Porongos Complex (Cerro da Árvore sequence).

Keywords: pre-collisional basins; metavolcanic rocks; crustal thickening; transpressive orogenic system; Dom Feliciano Belt

LISTA DE ILUSTRAÇÕES

- Figura 2. Diagrama de fase PT para o sistema termodinâmico onde H₂O é o único componente. 15
- Figura 3. Grade petrogenética calculada no software PERPLEX para o exemplo de Yardley (1989), onde os componentes do sistema são Na₂O, K₂O, SiO₂, Al₂O₃ e H₂O. Os campos divariantes são delimitados pelas linhas univariantes (reações metamórficas), sendo a assembleia mineral estável a maiores temperaturas representada no lado direito da equação. 16
- Figura 4. A) Trajetória PT-t típica de um overthrusting. B) Diagrama de temperatura x tempo da trajetória PT-t mostrada em A. C) Diagrama de taxa x tempo construído a partir de B. A taxa foi calculada utilizando $\Delta H = 250 \text{ kJ/mol}$ (Fonte: Modificado de Spear, 1994). 18
- Figura 5. A) Modelo de pseudo-seção (Spear, 1994). Dentro dos campos divariantes, as isopleths indicam como composição X_{Fe} (Fe/Fe+Mg) da granada variam com a pressão e temperatura. Nesse exemplo as reações das curvas univariantes são mostradas. B) Exemplo real onde isopleths do teor de anortita em plagioclásio (X_{an}Pl) e teor de sódio em clinopiroxênio (X_{na}Cpx) foram combinadas para definir as condições de PT de uma rocha metamórfica (elipse amarela) (Modificado de Elvevold et al., 2014). 21
- Figura 6. Exemplo teórico de porfiroblasto de granada zonado. A borda da granada (G2) encontra-se em equilíbrio com a biotita da matriz (B2), no entanto, o núcleo da granada (G1) representa um evento pretérito a G2-B2. Assim, o equilíbrio da assembleia mineral granada-biotita deve ser calculado a partir da composição (expressa pelas isopleths) de G2 e B2 (Fonte: Spear & Peacock, 1989). 25
- Figura 7. Arranjo cristalográfico dos sítios dos ETRs em monazita (a) e em xenotima (b). Tetraedro de fosfato (PO₄) é mostrado em verde. O íon trivalente grande (esfera vermelha) na monazita ocupa um poliedro irregular O₉ que acomoda preferencialmente ETRs de maior raio, ou seja, ETRs-L a ETRs-M e Th⁴⁺. Na xenotima, o dodecaedro regular O₈ favorece entrada de Y e ETRs de raio menor e mais pesados – ETRs-P. C) Coeficiente de partição entre monazita e xenotima ($K_D = C_{\text{mon}} / C_{\text{xen}}$) para ETRs, U e Th. ETRs-L e ETRs-M em laranja; ETRs-P em verde; e actínídeos em azul. (Fonte: modificado de Engi, 2017). 28

Figura 8. A) A figura acima demonstra uma clara correlação entre o particionamento dos ETR-P entre granada-monazita, como apresentado por Hacker et al. (2019 e referências ali contidas). B) Este gráfico demonstra que há também uma dependência da temperatura no particionamento de ETR-P entre monazita e granada (Fonte: modificado de Hacker et al., 2019).	32
Figura 9. Experimento realizado por Rutherford no qual as partículas alfa, beta e gama foram identificadas (Fonte dos dados: IAEA: Nuclear Data Section, 2019).	36
Figura 10. Datação Sm–Nd ou Lu–Hf de granada–rocha total utilizando o método da isócrona. Nos eixos são mostrados as equações de decaimento para Sm–Nd, Lu–Hf e o caso geral (P/R). As composições atuais medidas definem uma linha reta - uma “isócrona” - cuja inclinação (m) determina a idade (t) de crescimento da granada e dos demais minerais da matriz. D = isótopo radiogênico; P = isótopo radioativo; R = um isótopo de referência estável não radiogênico (Fonte: modificado de Baxter & Scherer, 2013).	40
Figura 11. Exemplo de idade concordante em um diagrama Concórdia U/Pb, onde as idades independentemente medidas por U^{235}/Pb^{207} (eixo x), U^{238}/Pb^{206} (eixo y) e Pb^{206}/Pb^{207} (diagonal) possuem o mesmo valor (2900 Ma) e, por isso, plotam sobre a curva concórdia (linha azul) (Fonte: Gehrels, 2014).....	46
Figura 12. Exemplo de idade discordante em um diagrama Concórdia U/Pb, onde U^{235}/Pb^{207} (eixo x), U^{238}/Pb^{206} (eixo y) e Pb^{206}/Pb^{207} (diagonal) possuem valores diferentes (2340, 2600 e 2820 Ma). Em detalhe, três amostras discordantes ilustrando que o efeito da discordância é menor sobre a idade Pb^{206}/Pb^{207} (Fonte: Gehrels, 2014).	47
Figura 13. Valores típicos de $\delta^{18}O$ para diferentes rochas e minerais; além da água do mar (padrão VSMOW, ou seja, $\delta^{18}O=0$) e água meteórica (Fonte: Modificado de Eiler, 2001; e Valley et al., 2005).	51
Figura 14. Valores $\delta^{18}O$ medidos em zircão de rochas máficas e ultramáficas. A) megacristais da região de Kimberley; e B) outras amostra de diferentes regiões do mundo (Fonte: modificado de Valley, 2003).....	54
Figura 15. $\delta^{18}O$ em zircão comparados ao conteúdo de sílica de 35 amostras da Província Superior, no Canadá. Note que o teor de $\delta^{18}O$ no zircão permanece similar, mesmo o teor de sílica sendo bastante variável. A maioria das amostras são tonalitos, trondhjemitos e granodioritos (TTG) e rochas vulcânicas associadas com $\delta^{18}O$ médio de 5.5 ± 0.7 (1 SD) (Fonte: modificado de Valley et al., 2005).	55
Figura 16. Compilação $\delta^{18}O$ vs idade obtidos em zircão de mais de 1200 rochas. Valores no arqueano são muito mais uniformes e próximos do manto ($5,3 \pm 0,3\%$), enquanto, após	

2,5 Ga, valores de $\delta^{18}\text{O}$ superiores a 7,5‰ são observados. Períodos de crescimento de supercontinentes são mostrados por barras na porção inferior: P - Pangea; G - Gondwana; R - Rodinia. LTB - Bombardeio Tardio, CEE - Terra primitiva fria e O_2 - aumento de oxigênio na atmosfera (Fonte: modificado de Valley et al., 2005). 57

Figura 17. Diagrama concórdia U-Pb dos grãos analisados por Booth et al. (2005), em vermelho, com valores de $\delta^{18}\text{O}$ medidos, indicado em negrito. A textura representativa de cada grupo de grãos também é indicada (Fonte: Booth et al., 2005). 58

ESTRUTURA DA TESE

Esta tese de doutorado está estruturada em três artigos submetidos em periódicos classificados nos estratos Qualis-CAPES A1, conforme as normas estabelecidas pelo Programa de Pós-Graduação em Geociências da Universidade Federal do Rio Grande do Sul. A sua organização compreende as seguintes partes principais:

TEXTO INTEGRADOR:

Na primeira parte da tese é apresentado o texto Integrador composto pelos seguintes capítulos: introdução; objetivos da pesquisa; os materiais e métodos utilizados; o estado da arte do tema da pesquisa; resumo dos resultados; considerações finais; referências bibliográficas.

O tema abordado no estado da arte foi o arcabouço teórico necessário para a realização de estudos de "petrocronologia". O crescente emprego e a escassez de bibliografia em língua portuguesa embasaram a escolha deste tópico em detrimento de outros assuntos também importantes, tal como orogênese, por exemplo. O estado da arte está organizado a partir de quatro tópicos principais: i) introdução à petrocronologia; ii) conceitos termodinâmicos aplicados às rochas metamórficas; iii) petrocronologia da monazita vs granada; iv) geologia Isotópica.

ARTIGOS:

Na segunda parte da tese são apresentados os artigos científicos. Os manuscritos são idênticos aos submetidos, porém as figuras foram dispostas dentro do texto, para facilitar sua leitura. As tabelas são apresentadas ao fim de cada manuscrito.

O primeiro artigo intitulado, "*Reconstruction of a volcano-sedimentary environment shared by the Porongos and Várzea do Capivarita Complexes at 790 Ma, Dom Feliciano Belt, southern Brazil*" de Battisti, M.A.; Bitencourt, M.F.; Schmitt, R.S., Nardi, L.V.S.; Martil, M.M.D.; De Toni, G.B.; Pimentel, M.; Armstrong, R.; Konopásek, J., foi submetido ao periódico *Precambrian Research*.

O segundo artigo, intitulado “*Petrochronology of the central Dom Feliciano Belt foreland, southernmost Brazil*” de Battisti, M.A.; Konopásek, J; Bitencourt, M.F.; Sláma, J. Percival, J.J.; De Toni, G.B.; Carvalho da Silva, S.; Costa, E.O.; Trubač, J., foi submetido ao periódico *Journal of Metamorphic Geology*.

O terceiro artigo, intitulado “*Unravelling major magmatic episodes from metamorphic sequences of the Dom Feliciano Belt central sector, Brazil – a comparative study of geochronology, elemental geochemistry, and Sr-Nd data*” de Battisti, M.A.; Bitencourt, M.F.; Nardi, L.V.S.; Florisbal, L.M.; Ackerman, L.; Sláma, J.; Padilha, D. F., foi submetido ao periódico *Lithos*.

ANEXOS:

Na terceira parte da tese são apresentados anexos com os dados complementares de cada artigo. Por fim, é apresentado o resumo do artigo intitulado “*Dissolution precipitation creep as a process for the strain localisation in mafic rocks*” de Lee, A.; Stünitz, H.; Soret, M.; Battisti, M. A. publicado no *Journal of Structural Geology*, desenvolvido durante período de intercâmbio na UiT–*The Arctic University of Norway*.

1. Introdução

A arquitetura original de ambientes pré-colisionais é difícil de reconstruir devido aos processos atuantes durante as colisões (e.g. Cawood et al., 2009; Vanderhaeghe, 2012; Chetty, 2017), incluindo intensa deformação, e também devido ao posicionamento de magmas pós-colisionais que mascaram as antigas relações pré-colisão. Assim, bacias pré-colisionais têm sua estratigrafia original comumente bastante modificada durante a deformação (Tavani et al., 2015; Lacombe & Bellahsen, 2016). Além disso, em cinturões de dobras e cavalgamentos (*fold-and-thrust belts* – e.g. Boyer & Elliott, 1982; Sanderson, 1982) fatias de litologias alóctones podem ser transportadas por centenas de quilômetros, muitas vezes causando inversão da estratigrafia original e colocando rochas de alto grau sobre as de baixo grau metamórfico, como pode ser observado nos Himalaias, por exemplo (Harrison et al., 1999). A determinação precisa de tais eventos metamórfico-deformacionais também é essencial para a correta interpretação da evolução dos cinturões orogênicos. No entanto, uma dificuldade que surge dessa questão é que em terrenos metamórficos com evolução prolongada, a separação de eventos de deformação distintos sob um mesmo período de deformação progressiva, às vezes é de difícil reconhecimento devido à superposição de estruturas deformacionais e mineralogia metamórfica semelhantes (e.g. Fossen et al., 2019).

O Cinturão Dom Feliciano que se estende da margem leste do sul do Brasil até o Uruguai engloba todas as problemáticas acima discutidas, uma vez que constitui um cinturão de dobras e cavalgamentos no qual a deformação progressiva teve papel crucial na sua estruturação (e.g. Oriolo et al., 2016; Martil et al., 2017; De Toni et al., 2020a) e dispõe um extenso magmatismo pós-colisional (e.g. Bitencourt & Nardi, 1993, 2000). A complexidade da evolução do cinturão é destacada por trabalhos recentes, seja no que tange a sua configuração pré-colisional em ca. 800-770 Ma, interpretada tanto como arco maduro (Koester et al., 2016; Martil et al., 2017; Battisti et al., 2018) ou como rifte/bacia de retro-arco (Konopásek et al., 2018, 2020; Will et al., 2019); seja no que tange seu período contracional de prolongada duração, de ca. 650 Ma até <ca. 570 Ma (Philipp et al., 2016b; Oriolo et al., 2016; Battisti et al., 2018; De Toni et al., 2020a, 2021; Percival et al., 2021, 2022). No setor central do Cinturão Dom Feliciano, Rio Grande do Sul, Brasil, algumas relações não muito bem entendidas entre diferentes unidades geológicas provém dessa evolução complexa. Por exemplo, alguns autores sugeriram recentemente uma conexão entre uma porção

das rochas do antepaís (Complexo Porongos) e do além-país (Complexo Várzea do Capivarita) do Cinturão Dom Feliciano (Martil et al., 2017; Battisti et al., 2018; De Toni et al., 2020b). Possíveis relações entre os complexos Porongos e Passo Feio também foram recentemente sugeridas (Souza, 2020; Costa et al., 2021). No entanto, o significado geológico das relações entre essas três unidades ainda carece de maiores informações, principalmente envolvendo a conexão entre os Complexos Porongos e Passo Feio.

Dessa forma, a presente tese buscou avaliar a história pré-colisional e colisional do setor central do Cinturão Dom Feliciano com base no estudo da relação espacial e temporal dos complexos Porongos, Várzea do Capivarita e Passo Feio. Apesar da dificuldade de se estudar tais situações geológicas, conforme discutido acima, algumas abordagens foram escolhidas com a finalidade de resolver as questões em aberto:

Com o intuito de investigar a história pré-colisional do Cinturão Dom Feliciano, no artigo 1 estudos geocronológicos e de isótopo de oxigênio em zircão foram analisados em rochas metavulcânicas intercaladas com as sequências metassedimentares dos complexos Várzea do Capivarita e Porongos. Os resultados sugerem novas interpretações para a história pré-colisional desse cinturão e trouxeram robustas evidências de uma conexão pré-colisional, em ca. 800-770 Ma, entre as rochas do antepaís (uma porção do Complexo Porongos) e do além-país (Complexo Várzea do Capivarita) do Cinturão Dom Feliciano.

Com o intuito de investigar a história colisional do Cinturão Dom Feliciano, no artigo 2 uma abordagem de petrocronologia (Fraser et al., 1997) foi utilizada. Tal abordagem combina o estudo de geocronômetros com estudo petrológico e microestrutural detalhados, cujo intuito é correlacionar com precisão os minerais datados e o evento geológico associado a esse mineral (Engi et al., 2017; Yakymchuk et al., 2017). Essa abordagem foi escolhida devido a história deformacional complexa do Cinturão Dom Feliciano, apresentada anteriormente. O estudo de amostras metassedimentares dos complexos Porongos e Passo Feio através de estimativas P-T, datações de isócrona Lu-Hf granada-rocha total e de U-Pb *SIMS* em monazita permitiu estabelecer dois períodos distintos de espessamento crustal no Cinturão Dom Feliciano, o primeiro em ca. 660 Ma e o segundo em ca. 565 Ma. Os dados trouxeram evidências de migração para oeste da frente orogênica em um sistema orogênico transpressivo de longa duração (660–560 Ma).

Com o intuito de se obter informações adicionais sobre os ambientes sedimentares originais e investigar as possíveis relações entre os complexos Porongos, Várzea do Capivarita e Passo Feio, no artigo 3, dados de geoquímica elementar e de isótopos de Sr-Nd de amostras metavulcânicas intercaladas nas sequências metassedimentares desses três complexos foram compiladas da literatura. Novos dados de geoquímica e isótopos de Sr-Nd são apresentados para sete amostras metavulcânicas dos complexos Porongos e Passo Feio. A datação de duas destas amostras metavulcânicas por U-Pb LA-ICPMS em zircão permitiu estabelecer uma idade de ca. 580 Ma, para o magmatismo ácido do norte do Complexo Passo Feio. A comparação dos dados sugere uma relação pré-colisional em ca. 800-770 Ma entre os complexos Porongos e Várzea do Capivarita, e uma relação tardi-colisional em ca. 600-580 Ma entre os complexos Porongos e Passo Feio, fundamentada em geoquímica elementar e isótopos de Sr-Nd.

1.1. Objetivos

Este trabalho propõe uma abordagem integrada de diversas técnicas com a finalidade de discutir a relação espacial e temporal dos complexos Porongos, Várzea do Capivarita e Passo Feio por meio do estudo de dados existentes e novos dados de geocronologia, isótopos, geoquímica e modelamento de condições metamórficas. Os objetivos específicos estão apresentados a seguir:

i) Obter dados de geocronologia (U-Pb em zircão) e isotópicos (O/Sr-Nd) para as rochas ortometamórficas intercaladas nas sequências metamórficas dos complexos Porongos, Várzea do Capivarita e Passo Feio.

ii) Compilar os dados de geocronologia, de geoquímica elementar e isotópica disponíveis para os complexos Porongos, Passo Feio e Várzea do Capivarita.

iii) Determinar por meio de modelamentos termodinâmicos as condições PT do metamorfismo das rochas metassedimentares dos complexos Porongos e Passo Feio.

iv) Determinar a(s) idade(s) de metamorfismo das rochas metassedimentares dos complexos Porongos e Passo Feio por meio de isócronas Lu-Hf em granada-rocha total e análises de U-Pb em monazita.

1.2. Materiais e métodos

O tema proposto para essa tese foi abordado através da utilização integrada de diversas técnicas. A estratégia utilizada consiste em uma revisão bibliográfica, trabalhos de campo, coleta de amostras orientadas, análises petrográfica, geoquímica de rocha total, química mineral através de microanálises em sonda eletrônica, geocronologia e geologia isotópica, e modelamentos termodinâmicos.

1.2.1. Revisão bibliográfica

O Complexo Porongos (CP), principal objeto de estudo dessa tese, apresenta diversas questões geológicas em aberto. Conforme é apresentado por esse estudo, tais questões se estendem ao Complexo Várzea do Capivarita, uma vez que a gênese destes dois complexos está associada; e também ao Complexo Passo Feio, cuja evolução metamórfica está relacionada com a evolução do CP. A revisão bibliográfica de trabalhos clássicos no CP, como Jost & Bitencourt (1980), Porcher & Fernandes (1990), Saalman et al. (2006) e outros, permitiu resgatar indagações de aspectos ignorados pela literatura recente. Destaca-se, a hipótese de Jost e Bitencourt (1980) de que o Complexo Porongos fora formado originalmente por duas bacias sedimentares distintas. Tal hipótese se perdeu ao longo dos anos e voltou a ser levantada apenas recentemente por Höfig et al. (2018) e Battisti et al. (2018). A investigação mais aprofundada dessa questão desencadeou uma das principais problemáticas de pesquisa desta tese.

É importante salientar, no entanto, que os trabalhos mais recentes trouxeram enormes contribuições ao entendimento da geologia do complexo estudado nessa tese, principalmente devido aos novos dados geocronológicos levantados (e.g. Saalman et al., 2011; Pertille et al., 2015b, 2015a, 2017; Gruber et al., 2016a). O estudo destes dados também foi de enorme importância para o levantamento e discussões das hipóteses. Assim, a revisão bibliográfica possibilitou a convergência de hipóteses mais recentes, com o resgate de algumas hipóteses mais antigas que se mostraram de extrema relevância no entendimento da geologia do Cinturão Dom Feliciano.

1.2.2. Coleta de amostras e análise petrográfica

Para o artigo 1, foram coletadas amostras sistemáticas com intuito de estabelecer a idade do protólito ígneo do Complexo Várzea do Capivarita, bem como, adquirir informações sobre a idade deposicional de sua bacia original. Uma amostra do extremo leste do Complexo Porongos também foi coletada com intuito de se estabelecer a idade ígnea do protólito em uma região do complexo que carecia de dados geocronológicos.

No artigo 2, a coleta de amostras em um perfil Leste-Oeste na porção central do Cinturão Dom Feliciano permitiu investigar a evolução geológica e a trajetória PT-t dessa região a partir do estudo integrado de modelamento termodinâmico e geocronologia (Lu–Hf em granada-rocha total e U–Pb em monazita). A análise petrográfica permitiu identificar a paragênese metamórfica das rochas estudadas, além de outros aspectos, tais como feições de retrometamorfismo, porfiroblastos sin-cinemáticos, inclusões minerais etc., os quais foram de suma importância na discussão e interpretação dos resultados.

No artigo 3, a coleta das amostras foi realizada com intuito de se obter novos dados de geoquímica de rocha total e isótopos de Sr–Nd em regiões do Complexo Porongos e Complexo Passo Feio que careciam de dados. A análise petrográfica permitiu estabelecer o caráter metavulcânico/metavulcanoclástico das amostras estudadas.

1.2.3. Geoquímica de rocha total

Análises de geoquímica de rocha total foram utilizadas nos artigos 2 e 3 da presente tese. Para o artigo 2, com intuito de se realizar modelamentos termodinâmicos (ver adiante), foram obtidas análises de elementos maiores a partir de tabletes de pó de rocha em um instrumento modelo Rigaku RIX 2000 X-Ray no Laboratório de Fluorescência de raios-x da Universidade Federal do Rio Grande do Sul (UFRGS), Brasil e no AcmeLabs – Bureau Veritas Minerals, no Canadá. Para o artigo 3, elementos maiores e traços foram analisados no ActLabs – Activation Laboratories Ltd, no Canadá. Os elementos maiores foram obtidos por ICP-OES (*Inductively Coupled Plasma Optical Emission Spectrometer*), enquanto os elementos traços por ICP-MS (*Inductively Coupled Plasma-Mass Spectrometry*).

1.2.4. Geocronologia e geologia isotópica

Cinco sistemas isotópicos foram utilizados nessa tese, dos quais, dois foram empregados com intuito geocronológico: U–Pb e Lu–Hf; e três deles foram utilizados para avaliar processos mantélicos nas rochas ortometamórficas: Rb–Sr, Sm–Nd e O. Uma breve descrição dos procedimentos adotados em cada artigo são indicados abaixo. A descrição detalhada de cada método é apresentada no seu artigo correspondente.

i) No artigo 1, foram realizadas análises de U–Pb e O em zircão. Imagens de catodoluminescência foram obtidas para descrever os aspectos dos grãos selecionados e delimitar as regiões a serem analisadas. As análises de U–Pb foram realizadas nos equipamentos SHRIMP I, SHRIMP II e SHRIMP RG, enquanto as análises de oxigênio no SHRIMP SI, na *Research School of Earth Sciences (RSES)*, na *Australian National University*, na Austrália. Os dados de U–Pb foram reduzidos de maneira similar ao descrito por (Williams, 1998, e referências ali contidas) usando o macro do Excel SQUID-1 de Ludwig (2003). Os dados de oxigênio foram normalizados pelo padrão TEMORA II com $\delta O_{18} = 8.2\text{‰}$.

ii) No artigo 2, foram realizados estudos geocronológicos de U–Pb em monazita e Lu–Hf em granada-rocha total. Imagens de elétrons retro espalhados (*backscattering*) em monazita foram obtidas com o intuito de descrever os grãos e delimitar as regiões a serem analisadas por U–Pb. Tais imagens foram obtidas no microscópio eletrônico Zeiss Merlin Scanning, na *Faculty of Health Sciences da UiT The Arctic University of Norway*, na Noruega. As análises de U–Pb por espectrometria de massa de íons secundários em monazita foram realizadas por sonda iônica modelo Cameca IMS 1280 no laboratório NordSIM sediado no *Swedish Museum of Natural History*, em Estocolmo, na Suécia. As análises de Lu–Hf foram realizadas no instituto de geologia da *Czech Academy of Sciences* (análises químicas) e na *Faculty of Science, Charles University* (análises de MC–ICP–MS), em Praga, na República Tcheca.

iii) No artigo 3, realizou-se análises para geocronologia U–Pb em zircão, em conjunto com dados isotópicos de Rb–Sr e Sm–Nd em rocha total. Da mesma forma que no artigo 1, imagens de catodoluminescência foram realizadas a priori para o zircão no equipamento JEOL EPMA do instituto de geologia da *Czech Academy of Sciences* em Praga, na República Tcheca. As análises de U–Pb foram realizadas por HR–LA–ICPMS no equipamento *Thermo Scientific Element 2*. Os dados isotópicos de

Rb-Sr e Sm-Nd foram analisadas através de um espectrômetro de massa por ionização térmica (*TIMS*) Thermo *Triton Plus* na mesma universidade.

1.2.5. Microanálise de Sonda Eletrônica

Análises de química mineral foram utilizadas para o modelamento termodinâmicos de rochas parametamórficas (artigo 2). Tais análises foram feitas no Laboratório de Microsonda Eletrônica do Centro de Estudos em Petrologia e geoquímica (CPGq), da UFRGS. O instrumento utilizado foi uma Microsonda Cameca SXFive com condições analíticas de 15 keV, 15 nA de corrente, e tamanho de feixe de 5 μm . O instrumento foi calibrado utilizando os seguintes padrões: diopsídio para os elementos Ca e Mg; rondonita para Mn; sanidina para Si, K e Al; Fe_2O_3 para Fe; albita para Na; rutilo para Ti; e Cr_2O_3 para Cr.

Os estudos de química mineral permitiram caracterizar os elementos maiores das fases minerais presente nas amostras, bem como calcular a fórmula estrutural destes. Além do mais, foi possível documentar a relação entre as fases minerais, e a presença de zoneamento químico em algumas dessas fases, conforme é relatado nos resultados desta tese.

1.2.6. Modelamentos termodinâmicos

Os modelamentos termodinâmicos foram elaborados para quantificar os parâmetros P e T do metamorfismo do Complexo Porongos e do Complexo Passo Feio. O método utilizado foi o de elaboração de pseudo-seções (Powell et al., 1998) utilizando a química de rocha total da amostra em questão, em conjunto com análises químicas pontuais dos minerais da paragênese metamórfica, através de microanálises de sonda eletrônica.

Os campos de estabilidade das assembleias minerais foram modelados utilizando o software *Perplex_X* 6.8.9 (Connolly, 2005, 2009), segundo a base termodinâmica publicada por Holland e Powell (1998 – atualizada em 2004). As soluções sólidas utilizadas para o modelamento termodinâmico foram: feldspato (Fuhrman & Lindsley, 1988), biotita, muscovita, clorita, estaurolita, cloritóide, cordierita e granada (White et al., 2014).

2. Estado da arte

2.1. Introdução à petrocronologia: “subindo em ombros de gigantes”

A petrocronologia é o ramo da geologia que visa entender a história evolutiva, termal, bária e química de uma rocha e/ou um evento geológico, através da utilização integrada de diversas ferramentas, tais como, a petrologia, o modelamento termodinâmico, a geocronologia e a química mineral (Engi et al., 2017). A petrocronologia, dessa forma, aborda não apenas a história termal de uma rocha metamórfica ou a idade de cristalização de um magma, por exemplo, mas se centra nos processos atuantes e nas taxas com que eles ocorrem nestes contextos (Engi et al., 2017). Os petrocronologistas defendem que a simples datação de um evento pode ser inútil em algumas situações geológicas, ao passo que, várias datações controladas, acompanhada de dados químicos e termodinâmicos, podem revelar diversos aspectos sobre a história evolutiva de uma rocha (Engi et al., 2017). O termo “petrocronologia” (Fraser et al., 1997) surge da necessidade dos petrólogos e geocronólogos em descrever essa abordagem única, que se preocupa em descrever e entender os processos ígneos e metamórficos. Em seu artigo pioneiro, por exemplo, Fraser et al. (1997) demonstraram que a quebra de fases minerais abundantes, tais como granada e anfibólio podem desencadear a formação de zircão, e desse modo, o dado geocronológico pode ser correlacionado à petrogênese e às estimativas de pressão e temperatura da rocha.

É importante salientar que a petrocronologia pode ser considerada “ciência irmã” da termocronologia. No entanto, segundo Engi et al. (2017), a petrocronologia normalmente se concentra nos processos que levam à formação de rochas ígneas e metamórficas – os minerais e texturas e os processos que as formaram – enquanto a termocronologia enfatiza os processos de resfriamento dos eventos ígneos, metamórficos e tectônicos (Engi et al., 2017). Uma vez que cada campo tenha suas características únicas e seus limites se sobreponham, elas são ciências complementares.

Um estudo de petrocronologia envolve, geralmente, a seguinte metodologia (Engi et al., 2017):

- i) Identificar um ou mais estágios específicos da evolução metamórfica, magmática e/ou estrutural em uma determinada amostra com base em critérios texturais, como sobrecrecimentos, inclusões, etc.

- ii) Documentar as relações de fase entre os minerais com base em análises de química mineral, usualmente através de microanálise de sonda eletrônica (*EPMA – em inglês*) ou espectrometria de massa com plasma acoplado indutivamente e ablação a laser (*LA-ICP-MS - em inglês*).
- iii) Usar técnicas de termobarometria, como modelamentos termodinâmicos e/ou geotermobarômetros empíricos, para restringir as condições de pressão-temperatura (PT) do equilíbrio da assembleia mineral.
- iv) Procurar relacionar uma ou mais zonas de crescimento específicas de um geocronômetro robusto adequado para cada estágio evolutivo. Essa etapa geralmente requer obtenção auxiliar de elementos traços nos minerais estudados, usualmente através de análises por EPMA ou LA-ICP-MS, ou pode, até mesmo, ser auxiliada por estudos isotópicos (e.g. isótopos de oxigênio em zircão).

Desta forma, o estado da arte desta tese visa descrever e discutir aspectos cruciais na aplicação da petrocronologia em rochas metamórficas, centrada principalmente nos tópicos III e IV descritos por Engi et al. (2017). Os itens I e II de Engi et al (2017) foram abordados sucintamente nos materiais e métodos, respectivamente nos tópicos “coleta de amostras e análise petrológica” e “microanálise de sonda eletrônica”.

2.2. Conceitos termodinâmicos aplicados às rochas metamórficas

Rochas metamórficas guardam evidências sobre a história geológica de uma rocha, incluindo informações sobre temperatura, pressão e, muitas vezes, deformação. Entende-se como metamorfismo o processo de mudança de mineralogia, composição química e/ou textura de uma rocha quando esta é submetida a um novo ambiente químico e/ou físico em qual sua associação mineralógica atual naquele tempo deixa de ser estável (Yardley, 1989). Por definição o metamorfismo ocorre no interior da crosta terrestre e no manto (Bucher & Grapes, 2011), e exclui os processos que levam a mudanças mineralógicas, químicas e físicas superficiais, como é o caso do intemperismo e dos processos associados a diagênese de rochas sedimentares (Yardley, 1989; Bucher & Grapes, 2011).

Durante o metamorfismo, as rochas são submetidas a dois tipos principais de mudanças: a substituição dos minerais originais por minerais metamórficos novos e

estáveis, em razão das reações químicas, e a recristalização de minerais já presentes, produzindo novas texturas, tais como a orientação de minerais lamelares ou o progressivo aumento de granulometria de alguma espécie mineral (Yardley, 1989). Ainda, um aspecto importante, e que faz parte da definição de metamorfismo, é o fato dessas mudanças ocorrerem essencialmente no estado sólido (Yardley, 1989; Bucher & Grapes, 2011). No entanto, Yardley (1989) destaca que pequenas quantidades de fluídos podem estar presentes nos poros da rocha durante o metamorfismo, os quais desempenham um papel muito importante ao facilitar as transformações metamórficas.

Ao decorrer da história evolutiva de uma rocha, a sobreposição e/ou recorrência de um ou mais eventos metamórfico-deformacionais é corriqueira e decifrar essa história evolutiva polifásica pode ser difícil. No entanto, em certas situações é possível obter informações desses diversos eventos e reconstruir uma trajetória evolutiva da rocha com base nas mudanças de pressão (P) e temperatura (T) com o passar do tempo geológico (t). Uma situação de preservação de diversos eventos pode se dar, por exemplo, através da preservação de minerais reliquiares de uma fase metamórfica pretérita inclusos nos minerais metamórficos do evento mais recente. O gráfico que representa os diversos pontos de P e T por qual uma rocha metamórfica passou durante a sua evolução ao longo do tempo (t) é conhecido como trajetória PT-t (do inglês, *PT-t paths*).

2.2.1. Trajetória PT-t

Um gráfico de pressão-temperatura-tempo (PT-t) visa reconstruir a trajetória de uma rocha metamórfica durante sua história evolutiva, através das informações pontuais de P e T que a mineralogia metamórfica da rocha fornece. Bucher & Grapes (2011) ilustram a trajetória de uma rocha em uma colisão continental (Fig. 1a), onde do tempo 1 (t_1) até o tempo 3 (t_3) o aumento da pressão é significativo, mas a temperatura permanece praticamente constante. Em t_3 a rocha atinge sua pressão máxima e um aumento de temperatura ocorre entre t_3 e t_4 , mantendo a pressão constante. Entre t_4 e t_5 ocorre uma descompressão acompanhada de aumento de temperatura, com continuada descompressão, porém acompanhada de diminuição da temperatura entre t_5 e t_6 . Plotando todos os pontos, de t_1 a t_6 , em um gráfico (Fig. 1b) é possível observar como a rocha variou suas condições de pressão e temperatura com o passar do tempo e, dessa forma, construir a sua trajetória PT-t.

Figura 1. A) Desenho esquemático da posição de uma unidade litológica na crosta em função do tempo durante uma colisão continental e a sua representação correspondente no espaço PT. B) Trajetória PT-t da rocha do exemplo mostrado em A (Fonte: Modificado de Bucher & Grapes, 2011).

Na figura 1b, é possível observar que a trajetória PT-t apresenta um sentido horário. Segundo Bucher & Grapes (2011) trajetórias PT-t de sentido horário são características de situações de metamorfismo regional orogênico e foram documentadas em diversos cinturões orogênicos pelo mundo, tais como, Alpes ocidentais, Apalaches e Himalaias. Muito frequentemente, a trajetória horária caracteriza a seguinte sequência de eventos: i) espessamento isotérmico; ii) aquecimento isobárico; iii) descompressão isotérmica e; iv) resfriamento isobárico (England & Thompson, 1984; Bucher & Grapes, 2011). Trajetórias PT-t no sentido anti-horário, no entanto, também existem, e tem sido relatadas em terrenos de fácies granulito onde um evento de aquecimento precede o espessamento crustal (Bucher & Grapes, 2011).

Idealmente, uma rocha registraria, através de sua mineralogia e texturas, informações de toda sua história evolutiva (de t_1 a t_6). Porém, a sobreposição de eventos metamórfico-deformacionais tende a apagar os registros dos eventos mais antigos. Isso ocorre porque uma rocha, quando submetida a novas condições de P e T, tende a reorganizar sua mineralogia a fim de obter o equilíbrio termodinâmico (Spear, 1994). As decorrências do equilíbrio termodinâmico na geração e na trajetória

evolutiva de rochas metamórficas tem sido alvo crescente de estudos a partir da década de 1980 (Spear et al., 2016). Alguns conceitos fundamentais de termodinâmica e como eles podem auxiliar no estudo das rochas metamórficas serão abordados nos tópicos seguintes.

2.2.2. Regra de fase e sistemas termodinâmicos

Rochas metamórficas são tratadas como sistemas em equilíbrio termodinâmico (Yardley, 1989), os quais são formados por um conjunto de “fases”. As fases de um sistema são formadas pela combinação de “componentes”. Componentes são os elementos, compostos ou misturas polifásicas que compõem um sistema. No caso de um sistema simples, em que água e gelo coexistam, por exemplo, ambos serão fases desse sistema, as quais se formam a partir de um mesmo componente: H₂O. À pressão ambiente de 1x10⁵ Pa, água e gelo coexistem à 0 °C apenas (Fig. 2). Em qualquer outra temperatura sob 1x10⁵ Pa, as fases não coexistirão. O mesmo vale se a pressão for alterada e a temperatura mantida em 0 °C, as fases também não coexistirão. Para coexistirem é necessário mudar pressão e temperatura juntas, de maneira dependente e isso significa que, quando água e gelo coexistem, esse sistema apenas possui um grau de liberdade, uma vez que se pode alterar apenas uma variável independentemente, ou P ou T, pois o valor da outra variável dependerá do valor escolhido para a variável selecionada. Como mostrado por Bucher & Grapes (2011) e Yardley (1989), a quantidade de graus de liberdade (variáveis independentes) de um sistema é definida pela Regra de Fase (Eq. 1 -Gibbs, 1878):

$$F = C - P + 2 \quad \text{Equação 1}$$

Onde, F é o número de graus independentes de liberdade do sistema, C é o número de componentes e P é o número de fases. Bucher & Grapes (2011) também destacam que, como consequência da regra de fase, o número de fases não pode exceder o número de componentes em mais de 2. No caso de um sistema água de um componente (H₂O) o número máximo de fases desse sistema será 3, representado pelo “ponto tríplice”, onde água, gelo e vapor coexistem (Fig. 2). O ponto tríplice possui 0 graus de liberdade ($C - P + 2 = 0$) e por isso é chamado de “ponto univariante”, uma vez que nem P, nem T podem ser alterados. As linhas 1, 2 e 3 da figura 2, possuem 1 grau de liberdade ($C - P + 2 = 1$) e são chamadas de “curvas

univariantes”. Os campos sólido, líquido e vapor, por sua vez, possuem 2 graus de liberdade ($C - P + 2 = 2$), e são chamados de “campos divariantes”, pois tanto P quanto T podem ser alterados independentemente sem que o equilíbrio do sistema seja desfeito.

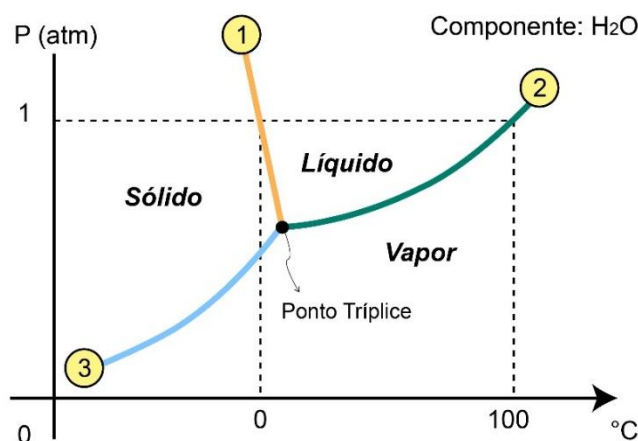

Figura 2. Diagrama de fase PT para o sistema termodinâmico onde H₂O é o único componente.

O diagrama que ilustra como se dá a disposição das fases em equilíbrio sob uma variada gama de pressões e temperatura de um sistema termodinâmico, como a exemplo da figura 2, é conhecida como “diagrama de fase P-T” (Bucher & Grapes, 2011). Os diagramas de fase também podem ser usados para ilustrar a variação de composição de uma fase (usualmente referida como “X”) em função da temperatura (“diagrama de fase T-X”) ou pressão (“diagrama de fase P-X”) de um sistema. Esses últimos dois casos são muito úteis para sistemas complexos com vários componentes, grupo no qual as rochas metamórficas estão inseridas.

Rochas são sistema termodinâmicos complexos pelo fato de comumente envolverem diversos componentes. Conforme exemplificado por Yardley (1989), em uma rocha com quatro fases minerais, como mica ((Na,K)Al₃Si₃O₁₀(OH)₂), quartzo (SiO₂), cianita (Al₂SiO₅) e feldspato ((Na,K)AlSi₃O₈), cinco componentes são exigidos para que todas essas fases coexistam em equilíbrio: Na₂O, K₂O, SiO₂, Al₂O₃ e H₂O. Neste exemplo, os cálculos termodinâmicos necessários para construir um diagrama de fase P-T são muito mais complexos do que os necessários para o exemplo da água/gelo. No caso de rochas, é possível construir diagramas PT utilizando as reações metamórficas para delimitar os campos de estabilidade dos minerais. Tais diagramas recebem o nome de “grade petrogenética” (Bowen, 1940) (e.g. Fig. 3). A ideia de Bowen era que, utilizando as curvas de reação univariantes, seria possível

delimitar todas as assembleias minerais divariantes em equilíbrio concebíveis para uma determinada composição química genérica (Bucher & Grapes, 2011). Cada assembleia mineral cairia, portanto, dentro de um campo único de P-T e indicaria as condições de metamorfismo da rocha (Bucher & Grapes, 2011).

Figura 3. Grade petrogenética calculada no software PERPLEX para o exemplo de Yardley (1989), onde os componentes do sistema são Na₂O, K₂O, SiO₂, Al₂O₃ e H₂O. Os campos divariantes são delimitados pelas linhas univariantes (reações metamórficas), sendo a assembleia mineral estável a maiores temperaturas representada no lado direito da equação.

As grades petrogenéticas idealizadas por Bowen (1940) foram revolucionárias para o estudo de petrologia metamórfica e tem como base as premissas estabelecidas pelo conceito de “estado de equilíbrio” termodinâmico, discutidas a seguir.

2.2.3. Estado de equilíbrio, pseudo-seções e geotermobarometria

Estado de equilíbrio é, segundo Spear (1994), o primeiro conceito fundamental para o estudo de rochas metamórficas sob a luz da termodinâmica. Segundo o mesmo autor, a base para este conceito vem do estudo cinético dos processos e reações metamórficas em uma rocha durante sua trajetória de pressão-temperatura. Tais processos cinéticos, em geral, seguem a Lei de Arrhenius (Eq. 2) que prediz a “taxa”

com que reações metamórficas ou difusões de minerais ocorrerão em uma rocha com relação a temperatura (Spear, 1994):

$$\text{Taxa} = A \exp\left(-\frac{\Delta H}{RT}\right) \quad \text{Equação 2}$$

Onde, A é uma constante pré-exponencial, ΔH é uma energia de ativação, R é a constante dos gases e T é a temperatura, em Kelvin.

Para ilustrar a importância de tal equação, Spear (1994) apresenta uma trajetória P-T (Fig. 4a) e o histórico T-t (Fig. 4b) de uma rocha em uma situação de *overthrusting*. O autor explica que a relação de Arrhenius (Eq. 2) prediz uma relação taxa-temperatura que pode ser projetada na curva temperatura-tempo da figura 4b e, dessa forma, representar uma curva de taxa-tempo (Fig. 4c). A figura 4c mostra que as taxas dos processos metamórficos são muito mais rápidas perto da temperatura do pico metamórfico e, portanto, as reações metamórficas e recristalização ocorrerão com muito mais intensidade perto dessa temperatura (Spear, 1994). Esse fato é de suma importância no estudo de rochas metamórficas, pois demonstra que a mineralogia e a química mineral comumente refletem as condições de pico metamórfico ao invés de qualquer outra parte da trajetória PT-t, onde as taxas dos processos são, pelo menos, dez vezes mais lentas (Spear, 1994). Dessa forma, na ausência de múltiplos eventos de aquecimento, as rochas metamórficas exibirão assembleias minerais e químicas minerais que refletem as temperaturas de pico metamórfico (Spear, 1994; Spear & Peacock, 1989). O exposto nas duas últimas sentenças explica o porquê da dificuldade de reconstruir a trajetória PT-t completa de uma rocha metamórfica.

Como demonstra a Lei de Arrhenius, para que as reações químicas em uma rocha ocorram, é necessário prover calor (energia, ΔH) ao sistema e aumentar sua temperatura. Segundo Spear & Peacock (1989), o calor necessário para elevar a temperatura de uma rocha durante o metamorfismo vem de três mecanismos gerais: i) condução (fluxo de calor de rochas quentes para rochas frias); ii) advecção (por exemplo, fluídos quentes se movendo através da rocha); e iii) fontes internas de calor (por exemplo, produção de calor radioativo). As reações metamórficas, por sua vez, são o resultado dos átomos do sistema rocha se reorganizando na configuração mais estável possível sob as novas condições de T e P impostas, ou seja, buscando o estado de equilíbrio termodinâmico (Yardley, 1989).

Figura 4. A) Trajetória PT-t típica de um *overthrusting*. B) Diagrama de temperatura x tempo da trajetória PT-t mostrada em A. C) Diagrama de taxa x tempo construído a partir de B. A taxa foi calculada utilizando $\Delta H = 250 \text{ kJ/mol}$ (Fonte: Modificado de Spear, 1994).

Rochas são más condutoras de calor, conduzindo-o de maneira bastante lenta e, por isso, grandes volumes de rochas levam milhões de anos para sofrerem mudanças de temperatura (Yardley, 1989). Mais precisamente Bucher & Grapes (2011) estimam que para metamorfozizar um pacote de 10 km de espessura de folhelho sob cerca de 400-600 °C, com um fluxo de calor de 40 mW/m², comum em situações de crosta continental, seriam necessários cerca de 8 milhões de anos. Se o fluxo de calor fosse de apenas 20mW/m², uma camada de folhelho de 20 km de espessura com temperatura inicial de 200 °C levaria 48 milhões de ano para atingir 600 °C. Dessa forma, o período de tempo típico para processos metamórficos de escala regional é da ordem de 10 a 50 milhões de anos (Bucher & Grapes, 2011). Os maiores fluxos de calor são registrados ao longo das dorsais meso-oceânicas (120 mW/m²), enquanto os mais baixos encontram-se nas regiões cratônicas (30 mW/m²) (Bucher & Grapes, 2011).

Embora o conceito de grade petrogenética (Bowen, 1940) tenha sido revolucionário no estudo das rochas metamórficas, naquela época, os estudos termodinâmicos em minerais eram escassos, fazendo com que as primeiras grades petrogenéticas fossem simplórias e não possibilitassem estimar as condições metamórficas de uma rocha com precisão (Bucher & Grapes, 2011). Atualmente os estudos termodinâmicos desenvolvidos por muitos autores (e.g. Berman, 1988; Holland & Powell, 1990, 1998; Johnson; Oelkers & Helgeson, 1992), principalmente após década de 80, geraram uma base de dados muito mais robusta (Spear et al., 2016). Utilizando tais bases termodinâmicas, alguns *softwares* permitem o cálculo de

grades petrogenéticas e pseudo-seções. Segundo Bucher & Grapes (2011), os 4 principais *softwares* utilizados pelos petrólogos metamórficos são: *TWQ/TWEEQU* (Berman, 1991), *DOMINO/THERIAK* (de Capitani & Petrakakis, 2010), *PERPLEX* (Connolly & Kerrick, 1987; Connolly, 1990) e *THERMOCALC* (Powell & Holland, 1985, 1988).

Pseudo-seções são diagramas bastante similares as grades petrogenéticas, porém ao contrário das últimas, as primeiras levam em conta a variação composicional (X) de uma fase dentro de um campo divariante. Dessa forma as grades petrogenéticas são diagramas PT enquanto as pseudo-seções são diagramas PT-X (Bucher & Grapes, 2011; Spear, 1994). Outra vantagem das pseudo-seções é que elas são calculadas com base na análise de rocha total específica da rocha estudada, e não para uma composição química genérica, como no caso das grades petrogenéticas. Além disso, uma vez que consideram a variação da “atividade” dos elementos de uma “solução sólida” dentro de um campo de estabilidade divariante, as pseudo-seções podem ser combinadas com geotermômetros para definir com maior precisão as condições metamórficas de uma rocha.

Dois conceitos do parágrafo acima são essenciais para o estudo de pseudo-seções, são eles: solução sólida e atividade (química). Uma solução sólida é uma mistura em estado sólido de dois ou mais componentes que constituem uma fase única (IUPAC, 2014). Muitos minerais formam soluções sólidas (feldspato, granada, piroxênio, anfibólio, etc), sendo o plagioclásio o exemplo mais trivial. Este mineral possui dois membros finais (*end-members*), Anortita (An_{90-100}) e Albita (An_{0-10}) e os membros intermediários Bytownita (An_{70-90}), Labradorita (An_{50-70}), Andesina (An_{30-50}) e Oligoclásio (An_{10-30}), com quantidades variáveis de Ca, Na, Al e Si (Deer et al., 2013). Em um sistema onde todos os elementos necessários ao plagioclásio estão disponíveis, a espécie de plagioclásio que cristalizará dependerá da atividade dos cátions Ca e Na ($a_{Ca,plag}$, $a_{Na,plag}$), as quais são variáveis em resposta a composição e as condições de pressão e temperatura deste sistema (Spear, 1994). O fato de muitas soluções sólidas possuírem sua química mineral influenciadas pela pressão e/ou temperatura é a principal premissa utilizada pela geotermobarometria.

Geotermobarometria é o nome dado a técnica que utiliza da dependência da constante de equilíbrio à pressão e temperatura para inferir pressões e temperaturas metamórficas (Spear, 1994). A constante de equilíbrio é dada pela equação abaixo (Eq. 3):

$$K_{eq} = \prod_j (a_{j,k})^{v_{j,k}} \quad \text{Equação 3}$$

Onde, K_{eq} é a constante de equilíbrio, $a_{j,k}$ é a atividade do componente j na fase k , e $v_{j,k}$ é o coeficiente estequiométrico do componente j na fase k . Conforme a definição de Spear (1994), essa equação é dependente da pressão e da temperatura, ou seja, para cada conjunto T e P o resultado da K_{eq} será diferente. Isso implica que a equação 3 possui infinitos resultados, devido as infinitas combinações possíveis de P e T (Bucher & Grapes, 2011). Isso significa também que a atividade de um elemento em uma mineral varia quando pressão e temperatura variam, exatamente como o exemplo do plagioclásio, acima. Apesar das infinitas respostas para a equação 3 é possível aplicar tal modelo termodinâmico pois cada solução para essa equação definirá uma linha em um diagrama PT (Spear, 1994), conhecida como *isopleth* (Fig. 5a). As *isopleths* podem ser calculados pelo mesmo *software* utilizado na elaboração da pseudo-seção. Dessa forma, as pseudo-seções preveem não só campo de estabilidade divariante de uma assembleia mineral, mas também como a composição de cada fase da assembleia mineral varia no interior daquele campo, conforme indicado pelas *isopleths*. Assim, de acordo com Spear (1994), aplicando modelos de atividade apropriados (e.g. Berman, 1988; Holland & Powell, 1990, 1998; etc) e aferindo com precisão e acurácia a composição dos minerais (i.e. química mineral) na rocha estudada (usualmente feito através de microanálise de sonda eletrônica) é possível estimar com precisão as condições metamórficas.

A constante de equilíbrio (Eq. 3) comumente é aplicada a diversos minerais de uma mesma assembleia simultaneamente (e.g. plagioclásio e piroxênio; granada, biotita e plagioclásio; etc). Tal metodologia resulta na obtenção de conjuntos de *isopleths* independentes, e logo, estimativas PT independentes para cada mineral utilizado. Segundo Spear (1994), a medida em que diferentes equilíbrios têm diferentes inclinações no espaço PT, a intersecção de dois ou mais equilíbrios (e.g. plg e cpx) pode ser usada para inferir um ponto PT (Fig. 5b). As inclinações variáveis ocorrem pois alguns equilíbrios são controlados por processos mais dependentes da pressão, enquanto, em outros, a temperatura é mais importante. Assim, a inclinação das *isopleths* resulta em uma relação de entropia e volume ($\Delta S_r/\Delta V_r$), conhecida como equação de Clausius-Clapeyron (Bucher & Grapes, 2011).

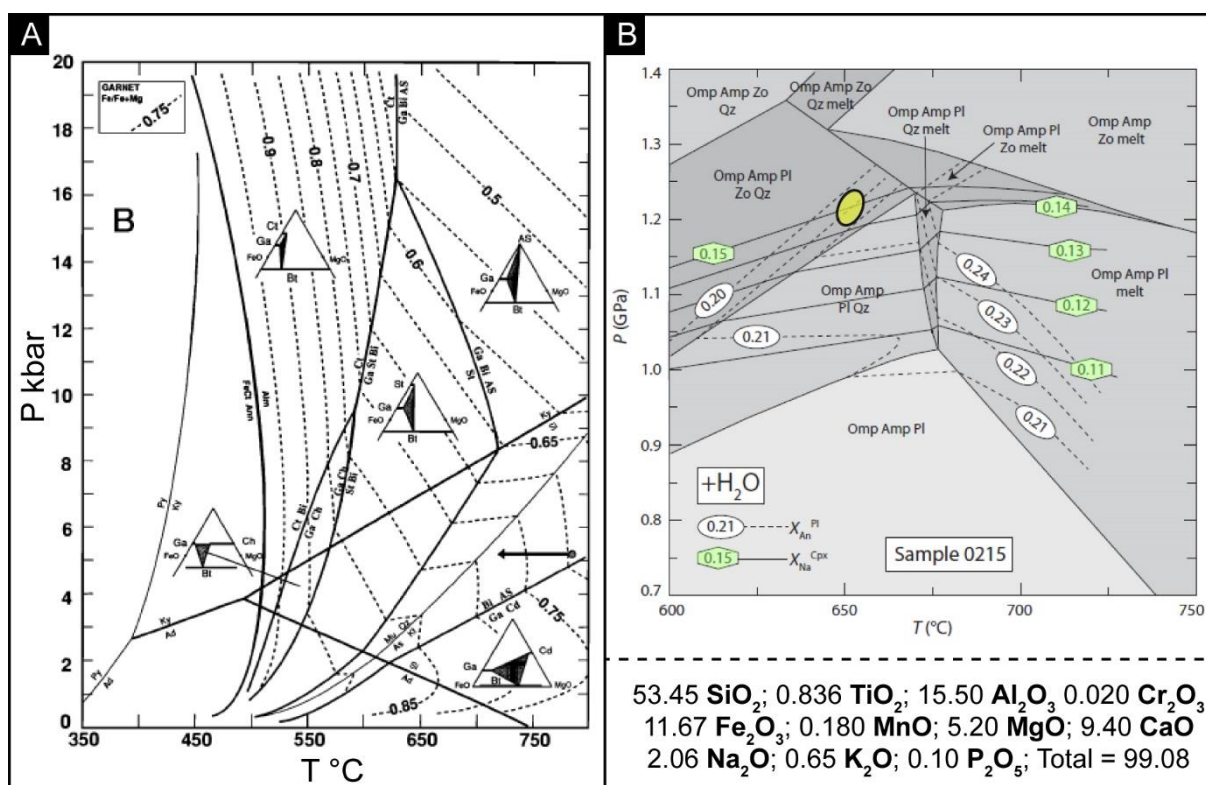

Figura 5. A) Modelo de pseudo-seção (Spear, 1994). Dentro dos campos divariantes, as *isopleths* indicam como composição X_{Fe} ($Fe/Fe+Mg$) da granada variam com a pressão e temperatura. Nesse exemplo as reações das curvas univariantes são mostradas. B) Exemplo real onde *isopleths* do teor de anortita em plagioclásio (X_{An}^{Pl}) e teor de sódio em clinopiroxênio (X_{Na}^{Cpx}) foram combinadas para definir as condições de PT de uma rocha metamórfica (elipse amarela) (Modificado de Elvevold et al., 2014).

Ainda com base na equação de Clausius-Clapeyron, os geotermobarômetros podem ser divididos em dois grupos: os geotermômetros e os geobarômetros. Geotermômetros são aqueles que são mais adequados para o cálculo de temperaturas geológicas e em geral, têm pouca dependência de pressão (Spear, 1994), resultando em *isopleths* verticais no espaço PT. Os geobarômetros são aqueles que são mais adequados para o cálculo de pressões geológicas e são relativamente insensíveis à temperatura (Spear, 1994), resultando em *isopleths* horizontais no espaço PT. Vale destacar, que *isopleths* de todas as inclinações são possíveis e, por exemplo, uma *isopleth* com inclinação de 45 graus reflete uma dependência do processo tanto à temperatura quanto à pressão.

A classificação dos geotermobarômetros também pode ser feita com base na natureza das reações químicas que o controla. Por exemplo, a troca de Ca e Na no plagioclásio em resposta às mudanças de temperatura ocorre através de trocas catiônicas dentro da mesma fase mineral, porém, existem outros tipos de

geotermobarômetros que podem inclusive trocar cátions com outras fases do sistema em equilíbrio. De acordo com Spear (1994) e Bucher & Grapes (2011), os tipos de geotermobarômetro são (*nomes originais mantidos entre parênteses*):

- Geotermobarômetro de troca catiônica (*Exchange Geothermometer*)

Os geotermobarômetros de troca catiônica baseiam-se na troca de dois átomos similares (raio e carga) entre diferentes sítios cristalográficos de um mineral (troca intracristalina) ou entre dois minerais distintos (troca intercristalina) (Bucher & Grapes, 2011). Muitos geotermômetros são baseados em reações de troca catiônica, envolvendo principalmente a troca de Fe e Mg entre silicatos coexistentes de uma assembleia mineral (Spear, 1994; Bucher & Grapes, 2011). As reações de troca geralmente envolvem pequena mudança de volume (ΔV pequeno), devido ao raio atômico similar dos cátions trocados, com moderados ΔS (entropia) e ΔH (entalpia), de forma que as *isopleths* tenham um declive relativamente íngreme, sendo portanto, bons geotermômetros (Spear, 1994).

A constante de equilíbrio para as reações de troca pode geralmente ser simplificada como sendo a razão dos cátions de uma fase dividida pela mesma razão na segunda fase (Spear, 1994). Esta formulação é definida como coeficiente de distribuição (K_D) que, para a troca de Fe e Mg entre as fases A e B, é definido como $K_D = (Fe/Mg)_A / (Fe/Mg)_B$ (Spear, 1994). Segundo Bucher & Grapes (2011) os dois exemplos de aplicação mais comuns são:

- i) Granada–Clinopiroxênio, dado pela reação piropo + hedenbergita = almandina + diopsídio, aplicado principalmente no estudo de granulitos e eclogitos;
- ii) Granada-Biotita, envolvendo a reação piropo + anita = almandina + flogopita, utilizado em rochas metamórficas de fácies xisto verde, anfíbolito e em alguns casos, granulito.

Além de diversos outros, tais como granada-cordierita, granada-horneblenda, granada-clorita, olivina-espinélio, ilmenita-olivina, ilmenita-piroxênio, etc (Spear, 1994; Bucher & Grapes, 2011).

- Geotermobarômetro *solvus* (*Solvus Geothermometer*)

Os geotermômetros *solvus* são embasados no fato de que alguns pares de minerais com estrutura semelhante mas com composição diferente mostram uma

solubilidade mútua que aumenta com o aumento da temperatura (Bucher & Grapes, 2011). Segundo Spear & Peacock (1989) essa terminologia é, no entanto, muitas vezes utilizada de maneira errônea, pois o termo “*solvus*” é restrito a fases isoestruturais, e muito dos geotermômetros chamados de “*solvus*” não obedecem a esta regra, como por exemplo o geotermômetro “dois-piroxênios” (Spear & Peacock, 1989). Este último é baseado na troca de Ca e Mg entre clinopiroxênio e ortopiroxênio e por isso, deveriam ser tratados como um geotermômetro de troca catiônica (Spear & Peacock, 1989). Os pares minerais comumente usados como geotermômetros *solvus* são ortopiroxênio–clinopiroxênio, feldspato alcalino-plagioclásio, calcita-dolomita e muscovita-paragonita (Bucher & Grapes, 2011).

- Equilíbrio de reações metamórficas (*Net Transfer Equilibria*)

Os geotermobarômetros desse tipo têm como base as reações químicas que ocorrem em estado sólido e ocasionam a transformação de uma fase mineral existente em outra fase mineral nova (Spear, 1994). As reações desse tipo podem ocorrer entre fases sólidas propriamente ditas (mineral A + mineral B = mineral C + mineral D) ou por reações de desvolatilização (mineral hidratado A = mineral desidratado B + H₂O) (Bucher & Grapes, 2011). Muitos desses equilíbrios geram excelentes geobarômetros pois comumente possuem mudanças de volume grandes (Spear, 1994; Bucher & Grapes, 2011). Outra vantagem é que essas reações delimitam equilíbrios multivariantes no espaço P-T-X e, como resultado, toda a assembleia termobarométrica pode coexistir em uma ampla faixa de P e T (Bucher & Grapes, 2011).

A aplicação desse tipo de equilíbrio como geobarômetro pode ser exemplificada pelo conjunto granada e plagioclásio. Tal geobarômetro envolve a troca de Ca entre o componente anortita do plagioclásio e o componente grossulária da granada (Bucher & Grapes, 2011). Uma vez que a anortita possui volume consideravelmente maior do que a grossulária, a estabilidade da grossulária é favorecida em altas pressões, ao passo que a estabilidade da anortita é favorecida em pressões menores (Bucher & Grapes, 2011). Para que o equilíbrio se mantenha, no entanto, outras fases são envolvidas nessa reação, como quartzo e aluminossilicato ($Gr + 2 Als + Qz = 3 An$) (Bucher & Grapes, 2011). Diversos outros geobarômetros do tipo *Net Transfer Equilibria* podem ser encontrados nos trabalhos de Bucher & Grapes (2011) e Spear (1994). Entre os principais utilizados estão Granada-Rutilo-

Aluminossilicato-Ilmenita-Quartzo - GRAIL ($1 \text{ Alm} + 3 \text{ Rt} = 3 \text{ Ilm} + 1 \text{ Als} + 2 \text{ Qz}$), Clinopiroxênio-Plagioclásio-Quartzo ($\text{Jd} + \text{Qtz} = \text{Ab}$) e Esfalerita-Pirrotita-Pirita.

2.2.4. Precauções no uso de modelamentos termodinâmicos

Uma vez que são baseados em modelos, sejam computacionais ou semi-empíricos, as pseudo-seções e os geotermobarômetros podem apresentar complicações e inconsistências. Por isso, um estudo petrográfico detalhado da mineralogia, das texturas, e da relação entre as fases minerais presentes na rocha estudada sempre será o primeiro e mais importante passo a ser dado em estudos de petrocronologia. Spear & Peacock (1989) e Bucher & Grapes (2011), descrevem algumas precauções que podem ser tomadas para que um bom resultado a partir do estudo de uma pseudo-seção possa ser obtido:

- i) A assembleia mineral deve ter se formado sob condições de equilíbrio termodinâmico

A suposição básica da geotermobarometria é que a assembléia mineral considerada se formou em equilíbrio (Bucher & Grapes, 2011). Porém é impossível provar que os minerais em uma rocha já atingiram o equilíbrio (Spear & Peacock, 1989; Bucher & Grapes, 2011). O desequilíbrio, por sua vez, por ser provado e, pelo menos três testes podem ser utilizados para isso (Spear & Peacock, 1989). A lógica desses testes é que, se não houver provas de desequilíbrio, a assembléia mineral está provavelmente em equilíbrio. Os testes são:

- Verificar a existência de minerais zonados. Caso existam, é necessário elucidar qual porção do mineral zonado está em equilíbrio com os demais minerais da rocha (Fig. 6).
- Verificar a consistência do particionamento de elementos em diferentes minerais em uma mesma lâmina e em outras amostras similares.
- Determinar se a temperatura e a pressão calculadas a partir do geobarômetro e do geotermômetro são consistentes para uma pequena área (e.g. diferentes amostra de um mesmo afloramento).

Contudo, subdomínios em desequilíbrio ou minerais zonados preservados em escala de lâmina podem representar diferentes estados de equilíbrio pelo qual a rocha

foi submetida e auxiliar na reconstrução da trajetória PT-t (Spear, 1994; Bucher & Grapes, 2011). Usualmente granadas zonadas, como o exemplo da figura 6, fornecem condições de dois pontos distintos da trajetória PT-t. O núcleo geralmente indica as condições de um evento pretérito ou início do crescimento deste mineral, enquanto a borda se reequilibra com a assembléia metamórfica da rocha (e.g. biotita) e fornece dados do evento mais jovem, ou dos estágios finais de crescimento desse mineral. Granada é um dos minerais mais utilizados em petrocronologia, pois seus baixos coeficientes de difusão permitem a preservação de zonação (Spear, 1994), uma vez que minerais como biotita se reequilibram totalmente nas condições PT impostas mais rapidamente (Ehlers et al., 1994). No entanto, destaca-se que o avanço das técnicas analíticas tem revelado que zonações são muito mais comuns do que se pensava a priori e ocorrem em diversas fases minerais (Spear et al., 2016).

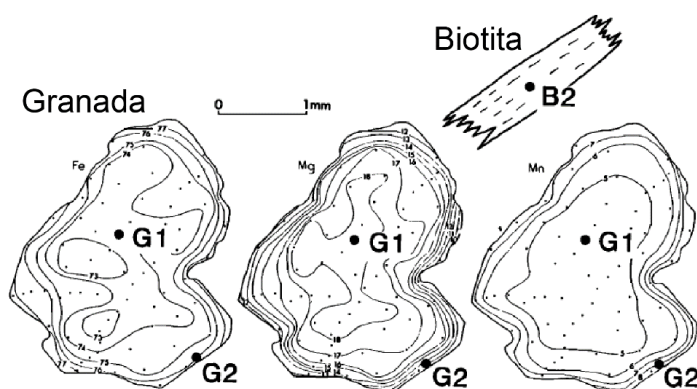

Figura 6. Exemplo teórico de porfiroblasto de granada zonado. A borda da granada (G2) encontra-se em equilíbrio com a biotita da matriz (B2), no entanto, o núcleo da granada (G1) representa um evento pretérito a G2-B2. Assim, o equilíbrio da assembleia mineral granada-biotita deve ser calculado a partir da composição (expressa pelas *isopleths*) de G2 e B2 (Fonte: Spear & Peacock, 1989).

ii) Retrometamorfismo

Caso a assembleia mineral de equilíbrio permaneça inalterada após sua formação, os valores de PT obtidos irão refletir as condições de pico metamórfico, como discutido por Spear (1994) e Spear & Peacock (1989). Bucher & Grapes (2011) destacam, no entanto, que tais situações devem ser válidas para algumas rochas rapidamente resfriadas ou de baixa temperatura, mas não se aplicam para rochas formadas em altas temperaturas e lentamente resfriadas, como o caso de granulitos, por exemplo. Nessas últimas, o retrometamorfismo (ou metamorfismo retrogressivo)

pode ter um papel bastante atuante (Bucher & Grapes, 2011). Em alguns casos, o retometamorfismo é claramente observado em lâmina (e.g. cloritização de biotita e granada). O problema, de acordo com Bucher & Grapes (2011), é que em outros casos, porém, esse processo pode ser observado apenas através de microanálise cuidadosa de sonda eletrônica. Segundo exemplos da literatura essas zonacões micrométricas formadas pelo retrometamorfismo podem causar alterações nos valores dos geotermobarômetros (e.g. Edwards & Essene, 1988).

iii) Qualidade do modelo/base termodinâmica utilizada

Como comentando anteriormente, existem diferentes modelos/bases termodinâmicos para minerais sendo, segundo Bucher & Grapes (2011), os de Berman (1988) e Holland & Powell (1990, 1998) os mais amplamente utilizados. A principal cautela a ser tomada a respeito da escolha do modelo termodinâmico é a de não utilizar os dados termodinâmicos para condições diferentes do que eles foram calibrados (Bucher & Grapes, 2011). Por exemplo, segundo os mesmos autores, a reação Grossulária + 2 Cianita + Quartzito = 3 Anortita foi experimentalmente determinada a temperaturas entre 900–1600 °C, porém, na prática, essa reação pode ocorrer até a 500 °C. Dessa forma, a aplicação desse geotermômetro para o segundo caso deve ser feita com precaução (Bucher & Grapes, 2011). Além disso, é necessário levar em conta a sensibilidade do geotermobarômetro, pois alguns sistemas são sensíveis apenas a uma faixa restrita de P e T (Bucher & Grapes, 2011). Fazem parte desse último caso muitos dos geotermômetros *solvus* que são úteis em temperaturas relativamente altas, mas menos proveitosos em temperaturas relativamente baixas (Bucher & Grapes, 2011).

iv) Estimativa da razão Fe^{2+}/Fe^{3+} nas análises minerais

As micronálises em sonda eletrônica fornecem o teor total de ferro expresso em FeO ou Fe₂O₃, e o teor do outro estado de valência deve ser calculado assumindo o equilíbrio de cargas e os sítios cristalográficos de cada mineral (Bucher & Grapes, 2011). Para algumas espécies minerais esses cálculos são bastante complexos, devido a presença de vacâncias cristalográficas e conteúdo variável de H₂O (por exemplo, anfibólios e clorita) (Bucher & Grapes, 2011). Dessa forma, o cálculo de

Fe^{2+}/Fe^{3+} requer dados de microsonda de excelente qualidade, a fim de minimizar ao máximo as incertezas nesses valores (Bucher & Grapes, 2011).

v) Efeitos de outros componentes

A grande maioria dos geotermobarômetros é baseada em equilíbrios minerais calibrados utilizando composições minerais simples, contudo, a maioria dos minerais em rochas contêm componentes adicionais e formam soluções sólidas complexas (Bucher & Grapes, 2011). Como consequência, muitas vezes há discordância entre os petrólogos sobre o modelo termodinâmico de solução sólida mais adequado para uma determinada espécie mineral (Bucher & Grapes, 2011). Como exemplo das complexidades geradas por componentes adicionais, pode-se citar a “difusão invertida” de elementos (*uphill diffusion*), discutida por Kohn & Penniston-Dorland (2017), entre outros autores.

As estimativas de condições metamórficas, seja por pseudo-seções ou geotermobarômetros, exige uma detalhada catacterização petrográfica, incluindo estudo de química dos minerais, e permite um bom entendimento da evolução de uma rocha metamamórfica quanto as suas condições de pressão e temperatura. A petrocronologia, no entanto, vai além, pois possibilita conectar esses estudos termodinâmicos com estudos de elementos traços, estudos isotópicos e de geocronologia desses minerais. Nesta tese foram utilizados Elementos Terras Raras para auxiliar na descrição evolutiva de granada e monazita, e as implicações da partição desses elementos entre esses dois minerais são discutidas a seguir.

2.3. Petrocronologia da monazita (*xenotima*) vs granada: partição de ítrio e Elementos Terras raras

Os elementos terras raras (ETRs) ou lantanídeos, são usualmente divididos em três grupos: i) Elementos Terras Raras leves (ETRs-L) – La, Ce, Pr e Nd; ii) Elementos Terras Leves médios (ETRs-M) – Sm, Eu, Gd e; iii) Elementos Terras Raras pesados (ETRs-P) – Tb, Dy, Ho, Er, Tm, Yb e Lu. O Y possui raio iônico dentro do intervalo dos ETRs-P e por isso é usualmente incluído neste grupo (Engi, 2017).

A monazita e a xenotima são referidas como ortofosfatos de íons grandes - (ETR)[PO_4], e fazem parte do grupo dos denominados “minerais de terras raras”, uma vez que os Elementos Terras Raras e ítrio são constituintes cruciais na formação

desses minerais (Engi, 2017). Na monazita, o íon trivalente de raio grande é coordenado com nove íons de oxigênio (ETR) O_9 , formando um poliedro irregular; enquanto na xenotima, o Y (e outros ETR $^{3+}$) são coordenados com oito íons de oxigênio (Y) O_8 e formam um dodecaedro regular (Fig. 7 a,b - Engi, 2017). Tal diferença estrutural exerce grande influência no coeficiente de partição (K_D) dos ETRs entre esses minerais (Fig. 7c). Segundo Engi (2017), enquanto a monazita, monoclinica, favorece a entrada de ETRs-L, a xenotima, tetragonal (parte do grupo do zircão), favorece a entrada de ETRs-P. Os ETRs-L com raio iônico maior se alojam no poliedro de coordenação 9O da monazita, enquanto o Y $^{3+}$ e os ETR-P, de raio iônico menor, se acomodam melhor no poliedro menor de 8O da xenotima (Engi, 2017). Além disso, Ce (ou La) são constituintes cruciais na monazita, os quais podem ser substituído por outros ETRs-L e Sm (Engi, 2017). Para a xenotima, o componente crucial é o Y (ou algum ETRs-P, ou ainda, Gd).

Figura 7. Arranjo cristalográfico dos sítios dos ETRs em monazita (a) e em xenotima (b). Tetraedro de fosfato (PO_4) é mostrado em verde. O íon trivalente grande (esfera vermelha) na monazita ocupa um poliedro irregular O_9 que acomoda preferencialmente ETRs de maior raio, ou seja, ETRs-L a ETRs-M e Th^{4+} . Na xenotima, o dodecaedro regular O_8 favorece entrada de Y e ETRs de raio menor e mais pesados – ETRs-P. C) Coeficiente de partição entre monazita e xenotima ($K_D = C_{\text{mon}} / C_{\text{xen}}$) para ETRs, U e Th. ETRs-L e ETRs-M em laranja; ETRs-P em verde; e actinídeos em azul. (Fonte: modificado de Engi, 2017).

Tanto a monazita quanto a xenotima são minerais que incorporam fortemente o urânio no momento da formação, mas não incorporam o chumbo (e.g. Williams et al., 2007). Em ambos minerais, U^{4+} pode ser substituído por Th^{4+} , sendo que a maioria das monazitas apresentam $Th/U > 1$, enquanto na xenotima geralmente a razão $Th/U < 1$ (Engi, 2017). Na xenotima, os conteúdos de Th e U são mais baixos, mas tanto a monazita quanto a xenotima são passíveis de datação. A monazita normalmente contém Th (wt%) e U (ppm) em concentrações suficientes para combinar seus

sistemas de decaimento para geocronologia; enquanto para xenotima apenas a datação U–Pb é possível (Engi, 2017). A monazita é um mineral muito mais comum e estudado que a xenotima, no entanto, segundo Engi (2017), inclusões e relações de supercrescimento são freqüentemente observadas entre esses fosfatos-ETR e podem ser de grande utilidade para relacionar idades a reações de substituição e efeitos metassomáticos.

A granada, por sua vez, é considerada um supergrupo de trinta e dois minerais (*sensu* Grew et al., 2013), o qual é composto principalmente por alumonissilicatos (16 dos 32) de sistema, quase exclusivamente, cúbico (30 dos 32). A fórmula mineral da granada é escrita como $\{X_3\}[Y_2](Z_3)\varphi_{12}$; na qual X, Y, e Z se referem aos sítios dodecaédrico, octaédrico e tetraédrico, respectivamente, enquanto φ é dado por O, OH, ou F (Grew et al., 2013). O sítio cristalográfico X, pode abrigar os elementos Ca, Na, Mg, Mn^{2+} , Fe^{2+} e Y; o sítio Y pode abrigar os elementos Al, Mg, Fe^{3+} , Mn^{3+} , Si, Ti, Zr, V^{3+} , Cr^{3+} , Sb^{5+} , Sn^{4+} e Te^{6+} ; no sítio Z, os elementos possíveis são Si, Al, Fe^{3+} , Li, Zn, V^{5+} e As^{5+} (Grew et al., 2013).

Segundo Baxter & Scherer (2013) a granada é especialmente útil nos estudos petrocronológicos porque (i) o controle termodinâmico das condições de pressão-temperatura-composição (P-T-X) de seu crescimento é bem compreendido; (ii) a granada geralmente registra processos tectono-metamórficos progressivos, em vez de retrometamórficos; (iii) este mineral cresce em uma ampla gama de condições P–T–X, abrangendo diversos contextos tectônicos e tipos de rocha e; (iv) cristais de granada zonados preservam a química e potencialmente, idades distintas, abrangendo processos de milhões de anos. Além disso, a granada é frequentemente zoneada em elementos traços, com núcleos enriquecidos em ítrio (Y) e ETR-P (Baxter & Scherer, 2013; Kohn, 2014; Baxter et al., 2017). Esses elementos altamente compatíveis tendem a resistir ao reequilíbrio em temperaturas elevadas devido às suas baixas difusividades inter e intragranulares (Baxter et al., 2017). Assim o zoneamento de elementos traços é comumente preservado em fácies anfibolito superior e granulito, condições em quais o zoneamento de elementos maiores (como Ca, Fe, Mg e Mn) é frequentemente resetado (Kohn, 2014; Baxter et al., 2017). Segundo Baxter et al. (2017) e as referências nele contidas, a granada pode ser fortemente zoneada em ETR, bem como Y, Zr, Cr, P e As.

A monazita, no entanto, pode se cristalizar em situações de metamorfismo progressivo (Rubatto et al., 2006); ou em algum momento após o resfriamento da temperatura máxima do pico metamórfico, no caso de migmatização (e.g. Hagen-

Peter et al., 2016), ou até mesmo a partir da desestabilização de outros minerais no retrometamorfismo – tais como a granada e alanita, por exemplo (Bollinger & Janots, 2006; Baxter et al., 2017; Yakymchuk et al., 2017). Segundo Yakymchuk et al. (2017), a monazita e xenotima ocorrem desde condições diagenéticas até metamorfismo de fácies anfíbolito, granulito e eclogito. Quanto a origem, a monazita pode ter origem detrítica, produzida por reações de estado sólido, precipitada por fluídos ou cristalizada a partir do magma anatéitico (Yakymchuk et al., 2017).

A partição de Y e ETR entre granada e monazita tem sido objeto de estudo de diversos autores (e.g. Pyle et al., 2001; Pyle & Spear, 2003; Rubatto et al., 2006; Hacker et al., 2019), e fornece um par robusto para estudos de petrocronologia. A granada possui um alto coeficiente de partição para Y e ETRs (Bea et al., 1994; Rubatto et al., 2006) sendo o sumidouro mineral mais importante para os ETR-P e ítrio em rochas metamórficas (Bea et al., 1994). Dessa forma, devido aos altos coeficientes de partição entre granada e matriz, um cristal de granada em crescimento incorpora Y + ETR-P no seu núcleo (*i.e.* no início de seu crescimento) (Baxter et al., 2017). A concentração desses elementos diminuem em direção às bordas do cristal de granada, gerando perfis "em forma de sino", devido ao processo de fracionamento *Rayleigh* (Kohn, 2014; Baxter et al., 2017). Em contraste, os ETR-M e ETR-L geralmente exibem um ligeiro aumento em abundância em direção às bordas do cristal de granada, ou sequer mostram zoneamento (Baxter et al., 2017). Os mesmos autores, no entanto, argumentam que os perfis de ETR na granada podem ser mais complexos, devido a uma série de fatores que podem ocorrer durante o crescimento deste mineral. Tais fatores são, por exemplo, a disponibilidade limitada de ETR na rocha durante o metamorfismo progressivo, a reabsorção de cristais de granada, a quebra de fases acessória ricas em ETR durante o crescimento da granada (e.g. monazita e xenotima), infiltração de fluido rico em ETR, entre outros (Baxter et al., 2017). Devido a interferência desses fatores citados, investigar outros minerais auxiliares, tal como a monazita, se faz necessário para que a história evolutiva da paragénese mineral seja compreendida de maneira integrada.

Minerais acessórios como zircão, monazita, xenotima, apatita, epidoto e alanita também são repositórios importantes para ETR-P e Y (Baxter et al., 2017). Comumente, a concentração de Y na monazita é ~1,5 ordens de magnitude maior do que na granada (Bea et al., 1994). A xenotima tem concentrações de Y que são ~2 ordens de magnitude mais altas do que na monazita (Pyle et al., 2001). No entanto, segundo Baxter & Scherer (2013), na maioria dos casos, a granada é

substancialmente mais abundante modalmente do que a monazita e a xenotima e, portanto, a quebra ou o crescimento da granada exercerá controles de primeira ordem sobre o fornecimento de Y e ETR-P da rocha. A cristalização de zircão e monazita durante o crescimento da granada (*i.e.* metamorfismo progressivo) resultará em concentrações relativamente baixas de ETR-P e Y nesses minerais acessórios, pois esses elementos são particionados para a granada principalmente, devido sua grande abundância modal (Baxter et al., 2017; Yakymchuk et al., 2017). Em contraste, a quebra de granada durante o crescimento de minerais acessórios, tal como a monazita, pode resultar em novas zonas de crescimento enriquecidas em ETR-P e Y nesses minerais acessórios (*e.g.* Foster et al., 2004; Rubatto et al., 2006). Dessa forma, zonas de alto Y e alto ETR-P em monazita podem ser vinculadas a quebra de granada e podem refletir por exemplo, o evento de soterramento ou exumação de uma trajetória P–T (Baxter et al., 2017; Yakymchuk et al., 2017). De maneira geral, os padrões de ETR e Y da monazita frequentemente refletem uma forte partição com os principais minerais coexistentes na assembleia metamórfica, notavelmente granada e feldspato (Baxter et al., 2017; Yakymchuk et al., 2017).

Os cristais de monazita podem conter importantes informações sobre eventos de retrometamorfismo em uma rocha. O crescimento retrometamórfico *subsolidus* de monazita (\pm xenotima) às custas de alanita ou apatita + granada, por exemplo, foi documentado em vários casos e geralmente está relacionado ao influxo de fluido (Bollinger & Janots, 2006). Ainda, de acordo com Engi (2017), os primeiros cristais de monazita a se cristalizarem em uma sequência tendem a sequestrar Th e Y, enquanto as zonas mais externas (mais jovens) são mais empobrecidas nesses elementos, embora esses padrões possam ser bastante complexos.

No caso de reabsorção da granada durante o metamorfismo, se algum elemento liberado durante esse processo não puder ser prontamente incorporado nas fases do produto (*e.g.* monazita), uma pequena quantidade de granada pode precipitar novamente, incorporando preferencialmente esse elemento (Kohn, 2014; Baxter et al., 2017). Segundo os mesmos autores, em geral, tais elementos seriam aqueles que tendem a ser fortemente particionados na granada, incluindo Mn, Y, Lu e outros ETR-P. Em alguns casos, minerais secundários podem se formar em uma superfície de reabsorção de granada impulsionada pelo influxo desses elementos particulares (Baxter et al. 2017). Xenotima, por exemplo, foi observado circundando superfícies reabsorvidas de granadas, onde o fluxo localizado de Y (da granada reabsorvida) promove o crescimento de xenotima (*e.g.*, Gatewood et al., 2015). Nesse caso, há

uma ligação textural útil entre a superfície da granada reabsorvida e a xenotima da fase acessória neocristalizada, a qual revela uma conexão temporal entre esses minerais (Gatewood et al., 2015).

Hacker et al. (2019) investigaram em detalhe a partição de ETR entre os minerais granada e monazita. Os autores observaram uma dependência no coeficiente de partição dos elementos ETR-P entre esses dois minerais, a partir do estudo de rochas metamórficas com protólitos pelíticos e quartzo-feldspáticos. Segundo Spear & Pyle (2010) no campo de estabilidade de granada + biotita + silicato de alumínio \pm estauroлита (o caso das amostras de Hackler et al., 2019) o aumento da pressão e/ou a diminuição da temperatura causa o crescimento de granada e o consumo de monazita, e o teor de Y de ambos é previsto diminuir. No caso inverso, de diminuição da pressão e/ou aumento da temperatura, o teor de Y se eleva. Como resultado principal de seu trabalho, Hackler et al. (2019) demonstraram que a partição do par monazita-granada tem dependência da temperatura para ETR-P, do Dy até o Lu, e partição não sistemática para os ETR-L e ETR-M, do La ao Gd, conforme indicado na figura 8.

Figura 8. A) A figura acima demonstra uma clara correlação entre o particionamento dos ETR-P entre granada-monazita, como apresentado por Hacker et al. (2019 e referências ali contidas). B) Este gráfico demonstra que há também uma dependência da temperatura no particionamento de ETR-P entre monazita e granada (Fonte: modificado de Hacker et al., 2019).

Segundo Baxter et al. (2017), o referencial teórico dos estudos de petrocronologia pode ser fragmentado em dois grandes grupos: o prefixo “petro” envolve os assuntos abordados nos tópicos 2.2 e 2.3 desta tese. O sufixo “cronologia” representa o outro grupo, de crucial importância para situar os eventos metamórfico-deformacionais no tempo geológico. A geocronologia é abordada abaixo, no tópico 2.4 e seus subitens.

2.4. Geologia Isotópica: introdução

Segundo a Lei de Moseley, as propriedades físico-químicas de um elemento são uma função exclusiva de seu número atômico (número de prótons), e dessa forma, um mesmo elemento químico pode possuir variadas configurações de nêutrons em seu núcleo sem que suas propriedades físico-químicas sejam alteradas. Como o nêutron, no entanto, possui massa, o diferente número de nêutrons irá influenciar o peso atômico do elemento. As diferentes configurações de núcleo que geram um mesmo elemento químico com diferentes pesos atômicos são conhecidas como isótopos (mesmo número de prótons, diferente número de nêutrons) (Van Grieken & de Bruin, 1994).

Para que um elemento químico seja estável, a combinação de prótons e nêutrons precisa obedecer a um equilíbrio termodinâmico, sendo que, quanto menor a configuração energética do elemento, mais estável ele será (White, 2013). Caso esse equilíbrio não seja totalmente atingido um núcleo atômico se forma, mas será instável (White, 2013). Um mesmo elemento pode possuir diversos isótopos em equilíbrio (isótopos estáveis) e diversos em desequilíbrio (isótopos instáveis).

O fato de alguns isótopos serem estáveis e outros instáveis resulta com que a abundância de cada isótopo na natureza seja diferente, pois os isótopos instáveis tendem a desaparecerem, e a abundância dos isótopos estáveis dependerá da trivialidade do processo pelo qual este é formado (White, 2013). A tabela 1 ilustra a abundância isotópica natural relativa do oxigênio, rubídio, estrôncio, samário, neodímio, lutécio, háfnio, urânio, tório e chumbo, que foram os isótopos utilizados nessa tese.

Os núcleos dos isótopos instáveis com o passar do tempo, a fim de obter uma configuração mais estável, desintegram-se emitindo partículas, gerando o fenômeno conhecido como “decaimento radioativo”. O decaimento radioativo pode fazer com que um isótopo instável de determinado elemento químico (chamado de isótopo radioativo ou pai) decaia para um isótopo de outro elemento (isótopo radiogênico ou filho), caso emita prótons, como por exemplo o $^{238}_{92}\text{U}$ que decai para $^{234}_{90}\text{Th}$ ($^{238}_{92}\text{U} \rightarrow ^{234}_{90}\text{Th} + \frac{4}{2}\alpha$). Esse processo é a base de muitos estudos geocronológicos e será retomado no tópico 2.4.1.

Tabela 1. Abundância isotópica natural relativa dos principais isótopos dos elementos químicos utilizados nessa tese (Fonte dos dados: IAEA: Nuclear Data Section, 2019).

Isótopo*	Abundância Natural Relativa (%)	Peso Atômico (u)	Energia de Ligação (KeV)	Tipo de isótopo
$^{16}_8\text{O}$	99,757	15,9949	7979,206	Estável
$^{17}_8\text{O}$	0,038	16,9991	7750,728	Estável
$^{18}_8\text{O}$	0,205	17,9991	7767,097	Estável
^{85}Rb	72,17	84,9118	8697,0	Estável
^{87}Rb	27,83	86,9091	8711,0	Decai para ^{87}Sr
^{86}Sr	9,86	85,9092	8708,0	Estável
^{87}Sr	7,00	86,9088	8705,0	Estável
^{88}Sr	82,58	87,9056	8733,0	Estável
^{144}Sm	3,07	143,9120	8303,680	Estável
^{147}Sm	14,99	146,9149	8280,573	Decai para ^{143}Nd
^{148}Sm	11,24	147,9148	8279,633	Decai para ^{144}Nd
^{152}Sm	26,75	151,9197	8244,065	Estável
^{142}Nd	27,15	141,9077	8346,031	Estável
^{143}Nd	12,17	142,9098	8330,489	Estável
^{144}Nd	23,79	143,9190	8326,924	Decai para ^{140}Ce
^{146}Nd	17,18	145,9131	8304,093	Estável
$^{175}_{71}\text{Lu}$	97,401	174,9407	8069,141	Estável
$^{176}_{71}\text{Lu}$	2,599	175,9427	8059,021	Decai para $^{176}_{72}\text{Hf}$
$^{176}_{72}\text{Hf}$	5,26	175,9414	8061,360	Estável
$^{177}_{72}\text{Hf}$	18,60	176,9432	8051,836	Estável
$^{178}_{72}\text{Hf}$	27,28	177,9437	8049,444	Estável
$^{180}_{72}\text{Hf}$	35,08	179,9465	8034,932	Estável
$^{234}_{92}\text{U}$	0,0054	234,0409	7600,715	Decai para $^{230}_{90}\text{Th}$
$^{235}_{92}\text{U}$	0,7204	235,0439	7590,914	Decai para $^{231}_{90}\text{Th}$
$^{238}_{92}\text{U}$	99,2742	238,0507	7570,125	Decai para $^{234}_{90}\text{Th}$
$^{232}_{90}\text{Th}$	100	232,0380	7615,033	Decai para $^{228}_{88}\text{Ra}$
$^{204}_{82}\text{Pb}$	1,4	203,9731	7879,932	Decai para $^{200}_{80}\text{Hg}$
$^{206}_{82}\text{Pb}$	24,1	205,9744	7875,362	Estável
$^{207}_{82}\text{Pb}$	22,1	206,9758	7869,866	Estável
$^{208}_{82}\text{Pb}$	52,1	207,9766	7867,453	Estável

Os isótopos estáveis, por sua vez, possuem configuração em equilíbrio com a natureza e por isso não sofrem decaimento radioativo. No entanto, isótopos estáveis

leves de um elemento (aqueles com menores pesos atômicos) podem ser fracionados em relação aos isótopos estáveis pesados deste mesmo elemento (White, 2013). Por exemplo, a água (H₂O) possui os três isótopos estáveis de oxigênio, porém o isótopo ¹⁶O é mais leve que o ¹⁷O e ¹⁸O e logo, mais fácil de ser evaporado. Isso faz com que a relação ¹⁶O/¹⁸O da atmosfera, de um rio e de uma geleira, por exemplo, sejam todas diferentes entre si (e.g. Rodrigues & Fauth, 2015). De maneira similar o fracionamento isotópico ocorre nos variados ambientes geológicos. Como os minerais, e por consequência as rochas, são formadas por elementos químicos, os minerais absorvem diferentes isótopos de um mesmo elemento quando cristalizados e dessa forma, guardam importantes informações sobre o ambiente geológico em que foram formados. Uma importante premissa no estudo dos isótopos estáveis é a admissão de que os isótopos de elementos pesados como Pb²⁰⁷, Nd¹⁴⁴, Sr⁸⁷ não são fracionados, e portanto, não são separados pelos processos geológicos (fusão parcial, metamorfismo, intemperismo, cristalização fracionada), enquanto os isótopos leves, como O¹⁶, H¹, C¹² são fracionados até pela ação da gravidade (e.g. evaporação da água) (White, 2013). O campo de aplicação dos estudos isotópicos, sejam os estáveis ou os instáveis, é bastante vasto e envolve por exemplo, estudo de gêneses de minérios, dinâmica mantélica, hidrogeologia, evolução crustal, vulcanologia, paleontologia e outros (White, 2013).

2.4.1. Isótopos instáveis: decaimento radioativo e geocronologia

A radioatividade de elementos químicos foi descoberta acidentalmente na transição entre os séculos XIX e XX pelo químico Henri Becquerel, quando este estudava os efeitos da fluorescência no mineral pechblenda e percebeu uma liberação natural de energia do átomo de urânio, capaz de ionizar gases e atravessar corpos opacos (Brennan, 2000). Subsequentemente a descoberta de Becquerel, Marie e Pierre Curie constataram que alguns isótopos de rádio e polônio liberavam muito mais energia que os de urânio e denominaram essa energia de radiação. A radioatividade pode ser definida como o processo espontâneo de emissão de radiação durante a desintegração de um núcleo atômico instável, em outras palavras, quando este núcleo passa da condição de instabilidade para a de estabilidade (Brennan, 2000). Todas as substâncias radioativas tendem a formar substâncias estáveis com o passar do tempo, e nesse processo emitem radiação (Brennan, 2000).

Posterior a descoberta da radioatividade, na mesma década, o físico Ernest Rutherford estudou a emissão de radiação atômica mais detalhadamente e demonstrou que sob um campo magnético, a radiação pode ser repelida, atraída ou não sofrer interferência (Fig. 9). Com isso, o autor demonstrou que três tipos diferentes de radiação podem ser liberados: Alfa (α), Beta (β), e Gama (γ) (Brennan, 2000).

Radiação	Constituição	Carga	Massa (u)	Penetração	Exemplo
Alfa (α)	2 prótons e 2 nêutrons	+2	4	Baixa	${}_{92}^{238}\text{U} \rightarrow {}_{90}^{234}\text{Th} + {}_{2}^{4}\alpha$
Beta (β)	1 elétron	-1	0	Média	${}_{7}^{17}\text{N} \rightarrow {}_{8}^{17}\text{O} + {}_{-1}^{0}\beta$
Gama (γ)	Onda eletromagnética	0	0	Alta	${}_{31}^{67}\text{Ga}^* \rightarrow {}_{31}^{67}\text{Ga} + {}_{0}^{0}\gamma$

** elemento no estado excitado*

Figura 9. Experimento realizado por Rutherford no qual as partículas alfa, beta e gama foram identificadas (Fonte dos dados: IAEA: Nuclear Data Section, 2019).

A maior contribuição de Ernest Rutherford, no entanto, foi sua percepção de que a desintegração dos núcleos de um isótopo instável é sempre ocasionada a uma taxa constante, porém específica para cada isótopo (Rutherford & Soddy, 1902). Dessa forma, a probabilidade de desintegração de uma quantidade de isótopos radioativos pode ser expressa em função do tempo, e assim, representar um relógio natural do universo. Essa descoberta deu início a ciência conhecida como geocronologia (Brennan, 2000). A equação básica do decaimento radioativo é expressa por:

$$\frac{dN}{dt} = -\lambda N \quad \text{Equação 4}$$

Onde, N é o número de átomos radioativos (isótopo radioativo/pai) no tempo presente, em gramas ou mols, t é o tempo decorrido (idade a ser determinada), e λ é a constante de desintegração do átomo radioativo (White, 2013). Integrando a equação 4 acima, tem-se que:

$$\int_{N_0}^N \frac{dN}{N} = \int_0^t -\lambda dt \quad \text{Equação 5}$$

Onde N_0 é o número de isótopos radioativos em $t=0$. Resolvendo a integral da equação 5, tem-se que:

$$\ln \frac{N}{N_0} = -\lambda t \quad \text{Equação 6}$$

Que pode ser expressa como:

$$\frac{N}{N_0} = e^{-\lambda t} \quad \text{Equação 7}$$

Ou, mais comumente:

$$N = N_0 e^{-\lambda t} \quad \text{Equação 8}$$

A partir da equação 8, para calcular o tempo necessário para que o número de átomos radioativos diminua para a metade do número original, ou seja, quando $N/N_0 = 1/2$, a equação 8 pode ser reescrita como:

$$\ln \frac{1}{2} = -\lambda t_{1/2} \quad \text{Equação 9}$$

Logo:

$$t_{1/2} = \frac{\ln 2}{\lambda} \quad \text{Equação 10}$$

A equação 10 apresenta matematicamente o conceito de "meia-vida" ($t_{1/2}$), que é o tempo necessário para que metade dos núcleos radioativos de uma amostra desintegre-se, ou seja, o tempo que leva para essa amostra radioativa reduzir-se à metade (White, 2013). Uma vez que a constante de desintegração é intrínseca de cada isótopo, a "meia-vida" também é variável, podendo ir desde frações de segundos até bilhões de anos (Tabela 2), e isso exercerá enorme influência na abundância isotópica natural, pois, por exemplo, isótopos instáveis com meia vida de milissegundos (*e.g.* ^{19}N) tornam-se praticamente inexistentes na natureza. Destaca-se também que, visto que o decaimento radioativo é um processo que envolve apenas

o núcleo atômico, a meia-vida não varia com a pressão ou com a temperatura e nem depende da quantidade inicial de isótopos radioativos da amostra (White, 2013).

Tabela 2. Exemplos de constante de desintegração (λ) e meia-vida de alguns isótopos instáveis (Fonte dos dados: Faure (2000), White (2013) e IAEA: Nuclear Data Section, 2019).

Isótopo radioativo instável (pai)	λ	Meia-vida	Isótopo radiogênico estável (filho)
^{147}Sm	$6,54 \times 10^{-12} \text{ anos}^{-1}$	$1,06 \times 10^{11} \text{ anos}$	^{143}Nd
^{176}Lu	$1,87 \times 10^{-11} \text{ anos}^{-1}$	$3,76 \times 10^{10} \text{ anos}$	^{176}Hf
^{87}Rb	$1,42 \times 10^{-11} \text{ anos}^{-1}$	$4,8 \times 10^{10} \text{ anos}$	^{87}Sr
^{232}Th	$4,98 \times 10^{-11} \text{ anos}^{-1}$	$1,4 \times 10^{10} \text{ anos}$	^{208}Pb , ^4He
^{238}U	$1,551 \times 10^{-10} \text{ anos}^{-1}$	$4,47 \times 10^9 \text{ anos}$	^{206}Pb , ^4He
^{235}U	$9,849 \times 10^{-10} \text{ anos}^{-1}$	$7,07 \times 10^8 \text{ anos}$	^{207}Pb , ^4He
^{14}C	$1,245 \times 10^{-4} \text{ anos}^{-1}$	$5,70 \times 10^3 \text{ anos}$	^{14}N
^{18}F	$6,3 \times 10^{-3} \text{ minutos}^{-1}$	$1,09 \times 10^2 \text{ minutos}$	^{18}O
^{19}N	$2,55 \text{ segundos}^{-1}$	$0,271 \text{ segundos}$	^{18}O

A concentração do isótopo radiogênico/filho (D) de um sistema radioativo pode então ser determinada através da diferença do número de isótopos radioativos inicial (N_0) e o número de isótopos radioativos atual (N). Isso ocorre, pois em $t=0$ nenhum núcleo radioativo terá decaído, porém com o passar do tempo, os isótopos radioativos decairão e se transformarão em isótopos radiogênicos estáveis (D), e por consequência, a concentração de D aumentará em função do tempo às expensas de N. Assim, tem-se que:

$$D = N_0 - N \quad \text{Equação 11}$$

Isolando N_0 na equação 8, e substituindo na equação 11 se tem que:

$$D = Ne^{\lambda t} - N \quad \text{ou} \quad D = N(e^{\lambda t} - 1) \quad \text{Equação 12}$$

Onde, determinando-se N e D em laboratório, sendo λ conhecido, é possível calcular a idade (t) do sistema isotópico. No entanto, é necessário ainda considerar a provável presença do isótopo radiogênico em $t=0$, não pelo decaimento do isótopo

radioativo, e sim pelo simples fato de o isótopo radiogênico existir na natureza e poder ser incorporado na estrutura do mineral no momento de sua cristalização. Assim, temos a equação geral da geocronologia:

$$D = D_0 + N(e^{\lambda t} - 1) \quad \text{Equação 13}$$

Onde D_0 é a quantidade de isótopos radiogênicos originalmente presente.

2.4.1.1. Geocronologia do sistema Lu-Hf

O sistema Lutécio-Háfínio é baseado no decaimento de ^{176}Lu para ^{176}Hf , através da emissão de radiação beta ($_{-1}^0\beta$), com meia vida de $3,76 \times 10^{10}$ anos (37,6 bilhões de anos), como mostrado na tabela 2. O sistema Lu-Hf obedece a equação geral da geocronologia e dessa forma, para esse sistema, a equação 13 pode ser reescrita como:

$$^{176}\text{Hf} = ^{176}\text{Hf}_0 + ^{176}\text{Lu}(e^{\lambda t} - 1) \quad \text{Equação 14}$$

No entanto, devido a dificuldade de se determinar os valores absolutos de ^{176}Lu , $^{176}\text{Hf}_0$ e ^{176}Hf por espectrometria de massa, geralmente na prática são determinadas razões isotópicas. Para isso ser possível, a amostra precisa ser "contaminada" com um isótopo não radiogênico de concentração conhecida, chamado de "*spike*", e assim os valores dos demais isótopos podem ser determinados (ver Dickin, 2005). No caso do sistema Lu-Hf o isótopo escolhido para *spike* é geralmente o ^{177}Hf e, portanto, após as razões isotópicas serem determinadas em laboratório, a idade do sistema pode ser calculada a partir da equação:

$$\frac{^{176}\text{Hf}}{^{177}\text{Hf}} = \left(\frac{^{176}\text{Hf}}{^{177}\text{Hf}} \right)_0 + \frac{^{176}\text{Lu}}{^{177}\text{Hf}} (e^{\lambda t} - 1) \quad \text{Equação 15}$$

A equação 15 descreve a equação de uma reta, uma vez que pode ser escrita como $y = b + xm$, onde a inclinação da reta é determinada por $m = e^{\lambda t} - 1$. A variável b , ou seja $(^{176}\text{Hf}/^{177}\text{Hf})_0$, descreve onde a reta intercepta o eixo vertical y ($^{176}\text{Hf}/^{177}\text{Hf}$). O eixo horizontal do gráfico é representado por x ($^{176}\text{Lu}/^{177}\text{Hf}$) (Fig. 10).

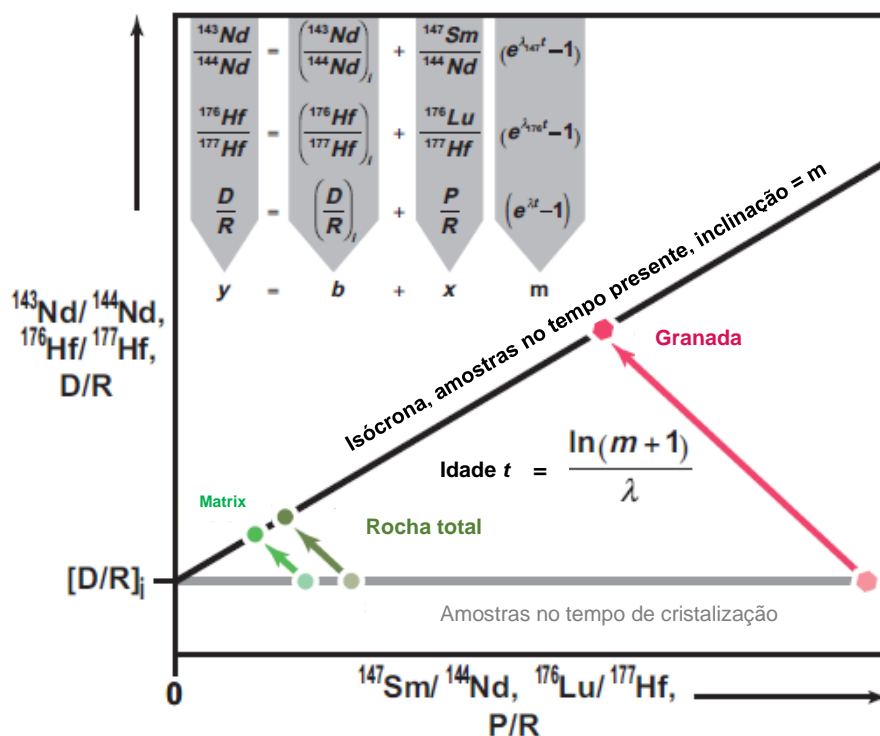

Figura 10. Datação Sm–Nd ou Lu–Hf de granada–rocha total utilizando o método da isócrona. Nos eixos são mostradas as equações de decaimento para Sm–Nd, Lu–Hf e o caso geral (P/R). As composições atuais medidas definem uma linha reta - uma “isócrona” - cuja inclinação (m) determina a idade (t) de crescimento da granada e dos demais minerais da matriz. D = isótopo radiogênico; P = isótopo radioativo; R = um isótopo de referência estável não radiogênico (Fonte: modificado de Baxter & Scherer, 2013).

Segundo Faure (2000), toda e qualquer idade de um sistema isotópico que possua a mesma razão inicial e a mesma idade (t), satisfazem a equação 15, e representam pontos sobre uma mesma reta no espaço $^{176}\text{Hf}/^{177}\text{Hf}$ vs $^{176}\text{Lu}/^{177}\text{Hf}$. Essa reta é dada pela inclinação $m = e^{\lambda t} - 1$ (Fig. 10), e é denominada de “isócrona”, uma vez que todos os pontos sobre ela apresentam a mesma idade t . A geocronologia utilizando o método de isócrona, no entanto, requer que todas as alíquotas/minerais analisados; (1) estiveram em equilíbrio isotópico, ou seja, com razão $(^{176}\text{Hf}/^{177}\text{Hf})_0$ idêntica no tempo t_0 e; (2) mantiveram-se em sistema fechado (sem perda de isótopo radioativo e/ou radiogênico), desde então (Baxter & Scherer, 2013). A idade t da isócrona pode ser calculada isolando t na equação $m = e^{\lambda t} - 1$:

$$t = \frac{1}{\lambda} \ln(m + 1) \quad \text{Equação 16}$$

Uma vez que qualquer dois pontos geram uma reta, Baxter & Scherer (2013) argumentam que usualmente combinam-se pelo menos três geocronômetros distintos

equilibrados isotopicamente. O equilíbrio isotópico pode existir entre minerais cristalizados simultaneamente, ou pode se dar através da difusão, ou recristalização de minerais preexistentes durante o metamorfismo (Baxter & Scherer, 2013). No caso de estudos geocronológicos em granada, comumente, realiza-se a medição adicional das razões Lu-Hf em rocha total, e em algum outro mineral da matriz (p.e ilmenita, piroxênio, etc), conforme ilustrado na figura 10, definindo-se três pontos distintos sobre a isócrona. No entanto, em certas situações, isócronas de dois pontos são aconselháveis, uma vez que preencher uma isócrona com dados adicionais não produzirá necessariamente uma idade mais precisa (Baxter & Scherer, 2013). A ausência de equilíbrio isotópico dos minerais analisados e/ou a abertura do sistema Lu-Hf, por exemplo, farão com que os pontos se dispersem para fora da isócrona, de forma que uma única reta não consiga descrevê-los (Baxter & Scherer, 2013).

2.4.1.2. Precisão e acurácia da isócrona Lu-Hf em granada

A granada é referida como “o petrocronômetro definitivo” (Baxter & Scherer, 2013) devido aos diversos aspectos que a tornam um excelente mineral para estudos de petrocronologia (e.g. robustez, baixo coeficiente difusão, etc). No entanto, a precisão e a acurácia das idades de isócrona Lu-Hf obtidas neste mineral requerem considerações.

A precisão das idades de isócrona Lu-Hf, segundo Baxter et al. (2017), depende da qualidade em limitar com precisão a inclinação da isócrona, a qual depende de três fatores principais: 1) a precisão analítica das razões isotópicas de cada ponto/mineral analisado, 2) a presença de pontos que possuem razão isotópicas (radioativo/radiogênico) diferentes (e.g. rocha total e granada) e 3) a dispersão dos pontos de razão isotópica mais baixa e os de razão mais alta ao longo da isócrona. Cristais de granada livres de inclusões tipicamente possuem razão $^{176}\text{Lu}/^{177}\text{Hf} > 1$, sendo essa razão normalmente maior que a da rocha total e dos demais minerais presente na rocha (e.g. ilmenita, piroxênio, etc) (Baxter & Scherer, 2013; Baxter et al., 2017). Assim, as análises de granada comumente constituem o ponto mais afastado da origem da isócrona, enquanto os outros pontos da reta isócrona, comumente representam o ponto mais próximo da origem (Baxter et al., 2017), conforme ilustrado na figura 10.

A acurácia do método de isócrona Lu-Hf envolvendo granada depende principalmente da eliminação dos efeitos das inclusões nos cristais de granada.

Segundo Baxter & Scherer (2013), os efeitos das inclusões de monazita, apatita e zircão em granada são bem documentados e variam de acordo com i) a idade das inclusões, ii) a razão $^{176}\text{Lu}/^{177}\text{Hf}$ das inclusões e iii) a concentração do elemento radiogênico destas inclusões. Segundo esses autores, inclusões com concentrações muito baixas de Hf raramente afetam as idades Lu-Hf da granada. Inclusões com baixa razão $^{176}\text{Lu}/^{177}\text{Hf}$ (por exemplo, zircão, que possui muito Hf) de mesma idade da granada irão deslocar o ponto de "granada" na isócrona para mais próximo da origem, degradando a precisão da idade, mas não afetando a acurácia (i.e. mesma idade, maior erro - Baxter & Scherer, 2013). No entanto, inclusões com idade substancialmente diferentes da idade da granada deslocam as análises de "granada" para longe da isócrona real, levando à perda de acurácia da idade analisada (Baxter & Scherer, 2013).

As inclusões devem, portanto, ser evitadas. A cautelosa separação de granada feita por catação manual elimina o efeito das inclusões maiores, no entanto não é suficiente para eliminar as micro inclusões. Segundo Baxter et al. (2017), os métodos de maior sucesso na eliminação das micro inclusões em granada envolvem o procedimento de 'lixiviação' (*leaching*) ou o de 'dissolução parcial'. Ambos os processos se utilizam de vários ácidos fortes e, no primeiro caso, dissolve-se as inclusões problemáticas em solução descartada, deixando a granada pura para análise, enquanto no segundo caso, dissolve-se a granada pura na solução analisada deixando as inclusões problemáticas no resíduo sólido. O primeiro procedimento é o mais empregado para a geocronologia Sm–Nd em granada, enquanto o segundo, é mais utilizado para idades Lu-Hf em granada (Baxter et al., 2017). Ainda, é importante frisar, que, conforme discutido por Baxter et al. (2017), não há evidências que sugiram que a lixiviação/dissolução parcial afetem a concentração dos elementos Sm–Nd e Lu–Hf da granada, e deste modo, não geram influência/erro nas idades obtidas.

Duas assertivas são utilizadas com a finalidade de verificar a eficiência na remoção das inclusões (Baxter & Scherer, 2013; Baxter et al., 2017). A primeira delas é que a granada livre de inclusões produz uma razão $^{176}\text{Lu}/^{177}\text{Hf} > 1$. Segundo Baxter et al. (2017), isso ocorre, pois, as inclusões contaminantes têm razões de isótopo radioativo/radiogênico muito mais baixas do que a granada hospedeira. A segunda é que a granada livre de inclusões exibe baixa concentração de Hf (<0.5 , e frequentemente $<0,1$ ppm) (Baxter & Scherer, 2013; Baxter et al., 2017). Dessa forma, Baxter & Scherer (2013) recomendam que os efeitos da contaminação por inclusões são suficientemente reduzidos quando a granada tem razão $^{176}\text{Lu}/^{177}\text{Hf} > 1,0$,

geralmente coincidindo com a concentração de Hf <1,0 ppm. Baxter et al. 2017, argumentam que esse limite é arbitrário, no entanto, serve como guia para estabelecer a confiança de uma determinada idade isócrona de granada.

2.4.1.3. Geocronologia do sistema U-Th-Pb

Enquanto a maioria dos sistemas isotópicos possuem apenas um isótopo radioativo que decai para um isótopo radiogênico (e.g. ^{176}Lu decai para ^{176}Hf), o sistema U-Th-Pb possui três sistemas de decaimento distintos: ^{238}U decai para ^{206}Pb , ^{235}U decai para ^{207}Pb e ^{232}Th decai para ^{208}Pb , com tempos de meia-vida também distintos (ver tabela 2) (Gehrels, 2014). Dessa forma, temos duas equações possíveis para o decaimento do urânio, uma para o ^{235}U e outra para o ^{238}U :

$$^{207}\text{Pb} = ^{207}\text{Pb}_0 + ^{235}\text{U}(e^{\lambda_{235} t} - 1) \quad \text{Equação 17}$$

e

$$^{206}\text{Pb} = ^{206}\text{Pb}_0 + ^{238}\text{U}(e^{\lambda_{238} t} - 1) \quad \text{Equação 18}$$

No entanto, no caso de minerais que incorporam fortemente o urânio no momento da formação, mas não incorporam o chumbo, como no zircão (ZrSiO_4) e na monazita $[(\text{Ce},\text{La},\text{Nd},\text{Th})\text{PO}_4]$, as equações 17 e 18 podem ser simplificadas pela remoção dos termos $^{207}\text{Pb}_0$ e $^{206}\text{Pb}_0$, respectivamente, para gerar (Dickin, 2005):

$$\frac{^{207}\text{Pb}}{^{235}\text{U}} = (e^{\lambda_{235} t} - 1) \quad \text{Equação 19}$$

e

$$\frac{^{206}\text{Pb}}{^{238}\text{U}} = (e^{\lambda_{238} t} - 1) \quad \text{Equação 20}$$

Segundo Scherer et al. (2007), o zircão seja talvez o geocronômetro mais versátil disponível, justamente porque durante a sua formação incorpora urânio (U) e tório (Th) em sua estrutura cristalina, mas exclui o chumbo (Pb). Além disso o zircão é um geocronômetro ímpar devido a sua robustez, pois é um mineral que pode permanecer intacto mesmo se sua rocha hospedeira for metamorfozada, fundida ou

sofrer desgaste mecânico (Scherer et al., 2007). Ainda, as taxas de difusão dentro do zircão para muitos elementos são extremamente baixas, de modo que este mineral normalmente retém a idade e outras informações isotópicas mesmo quando expostas a temperaturas magmáticas (Lee et al., 1997; Scherer et al., 2007). O uso da monazita como geocronômetro, por sua vez, é crescente desde o início do século XXI (Williams et al., 2007). Os principais fatores para esse crescimento, segundo Williams et al. (2007), são: i) a presença da monazita em uma ampla variedade de rochas ígneas, metamórficas e sedimentares; ii) o reconhecimento de que as taxas de difusão de muitos elementos na monazita são muito lentas; iii) a expansão e aperfeiçoamento de técnicas para análise e datação de monazita; iv) uma compreensão crescente das condições sob as quais a monazita pode cristalizar e recristalizar nas rochas; e v) um crescente entendimento das relações geoquímicas e petrológicas entre a monazita e os minerais silicáticos de uma rocha.

Os três sistemas de decaimento independentes transformam a datação por U-Th-Pb um método bastante robusto, pois três geocronômetros independentes, marcados pelas razões $^{206}\text{Pb}/^{238}\text{U}$, $^{207}\text{Pb}/^{235}\text{U}$ e $^{208}\text{Pb}/^{232}\text{Th}$, idealmente resultam na mesma idade t (Gehrels, 2014). No entanto, segundo Gehrels (2014) algumas considerações devem ser feitas:

i) A concentração de Th é geralmente baixa e a razão $^{208}\text{Pb}/^{232}\text{Th}$ dificilmente é utilizada (Gehrels, 2014). Na prática, então, a idade é calculada medindo-se três razões isotópicas apenas: $^{206}\text{Pb}/^{238}\text{U}$, $^{206}\text{Pb}/^{207}\text{Pb}$ e $^{206}\text{Pb}/^{204}\text{Pb}$; e, dessa forma, dois geocronômetros independentes: $^{206}\text{Pb}/^{238}\text{U}$, $^{207}\text{Pb}/^{235}\text{U}$ (Gehrels, 2014).

ii) Como visto no item i) a razão $^{207}\text{Pb}/^{235}\text{U}$ não é medida. Isso ocorre pois tal razão pode ser calculada de forma confiável (embora, controversa) a partir das razões $^{206}\text{Pb}/^{238}\text{U}$, $^{206}\text{Pb}/^{207}\text{Pb}$ e $^{238}\text{U}/^{235}\text{U}$. Uma vez que a razão $^{238}\text{U}/^{235}\text{U}$ é constante na natureza (137,82), a razão $^{207}\text{Pb}/^{235}\text{U}$ pode então ser calculada pela fórmula abaixo (Gehrels, 2014):

$$\frac{^{207}\text{Pb}}{^{235}\text{U}} = \left(\frac{\frac{^{206}\text{Pb}}{^{238}\text{U}}}{\frac{^{206}\text{Pb}}{^{207}\text{Pb}} * 137.82} \right) \quad \text{Equação 21}$$

iii) A razão $^{206}\text{Pb}/^{204}\text{Pb}$ é comumente medida de modo que as razões $^{206}\text{Pb}/^{238}\text{U}$ e $^{206}\text{Pb}/^{207}\text{Pb}$ possam ser corrigidas para Pb incorporado no momento da cristalização (Gehrels, 2014).

iv) Das três razões isotópicas essenciais de medição, segundo Gehrels (2014), $^{206}\text{Pb}/^{207}\text{Pb}$ e $^{206}\text{Pb}/^{204}\text{Pb}$ são relativamente mais fáceis de serem determinadas no espectrômetro de massa, devido ao baixo fracionamento dos isótopos de chumbo durante a análise. Ao contrário, a determinação da razão $^{206}\text{Pb}/^{238}\text{U}$ é mais difícil de ser feita, pois o U e o Pb se comportam diferentemente durante as análises.

Outra consideração importante nos estudos de geocronologia em zircão e monazita é a preocupação constante quanto a perda de Pb radiogênico durante a vida geológica da amostra, seja por efeito de fluídos, metamorfismo, etc. Um estudo geocronológico ideal exige que o cristal se comporte como um sistema fechado e retenha a composição original de U e Pb do momento de sua cristalização/metamorfismo. Nessa situação ideal os dois cronômetros de U-Pb, calculados de maneira independente - $^{206}\text{Pb}/^{238}\text{U}$ e $^{207}\text{Pb}/^{235}\text{U}$ - e por consequência as três razões $^{206}\text{Pb}/^{238}\text{U}$, $^{207}\text{Pb}/^{235}\text{U}$ e $^{206}\text{Pb}/^{207}\text{Pb}$ - devem resultar exatamente na mesma idade (Gehrels, 2014). Um meio conveniente de exibir os dois cronômetros U-Pb, além das três razões acima citadas, é através de um diagrama denominado de “concórdia U-Pb”, ou simplesmente “concórdia” (Wetherill, 1956) (Fig. 11). Uma análise que plota em cima da curva concórdia é referida como “concordante” e é a situação ideal em geocronologia, pois indica que todas as três razões produziram idades semelhantes e a interpretação da idade é simples (Gehrels, 2014).

A perda de Pb durante a história evolutiva da rocha (sistema aberto), resulta em discordância entre as três razões independentemente determinadas gerando uma idade chamada de “discordante”. Em casos de grandes discordâncias (>10%) o cálculo da idade de cristalização/metamorfismo do mineral torna-se impossibilitada, pois a imprecisão da medida cresce com o aumento da discordância. A interação da rocha com fluídos é um dos fatores mais comumente responsável pela perda de Pb. Além desses, outros processos como danos gerados por radiação, fraturamento do cristal devido à expansão diferencial da rede cristalográfica, alívio de pressão, recristalização, reações químicas e lixiviação são alguns dos outros processos que podem levar a perda de Pb radiogênico (Lee et al., 1997). Idades discordantes plotam fora da curva concórdia nos diagramas de concórdia U-Pb (Fig. 12) e, devido as três idades serem diferentes, possuem interpretação mais complexa do que as idades concordantes (Gehrels, 2014).

Figura 11. Exemplo de idade concordante em um diagrama Concórdia U/Pb, onde as idades indecentemente medidas por $\text{U}^{235}/\text{Pb}^{207}$ (eixo x), $\text{U}^{238}/\text{Pb}^{206}$ (eixo y) e $\text{Pb}^{206}/\text{Pb}^{207}$ (diagonal) possuem o mesmo valor (2900 Ma) e, por isso, plotam sobre a curva concórdia (linha azul) (Fonte: Gehrels, 2014).

Como comentado acima, análises onde as três razões possuem mais de 10% de discordância são geralmente descartadas, no entanto, análises com discordância entre 1% e 10% são usualmente utilizadas. O impacto da perda de Pb resulta graficamente em um aumento da distância da curva concórdia, e as idades calculadas se tornam menos precisas à medida que o grau de discordância aumenta, porém este efeito é menos pronunciado para as idades $\text{Pb}^{206}/\text{Pb}^{207}$ (detalhe da Fig. 12) (Gehrels, 2014). Por essa razão, as idades de $\text{Pb}^{206}/\text{Pb}^{207}$ são geralmente as mais confiáveis para essas situações, embora, destaca-se que a idade verdadeira será sempre subestimada (Gehrels, 2014). Por exemplo, na figura 12, a idade da amostra seria de 2900 Ma caso não houvesse perda de chumbo, no entanto, com a perda de chumbo as idades $^{206}\text{Pb}/^{238}\text{U}$, $^{207}\text{Pb}/^{235}\text{U}$ e $^{206}\text{Pb}/^{207}\text{Pb}$ foram, respectivamente, 2340 Ma, 2600 Ma e 2820 Ma. Ou seja, a idade obtida pela razão $\text{Pb}^{206}/\text{Pb}^{207}$ é o valor mais próximo do valor real de 2900 Ma, embora subestimado.

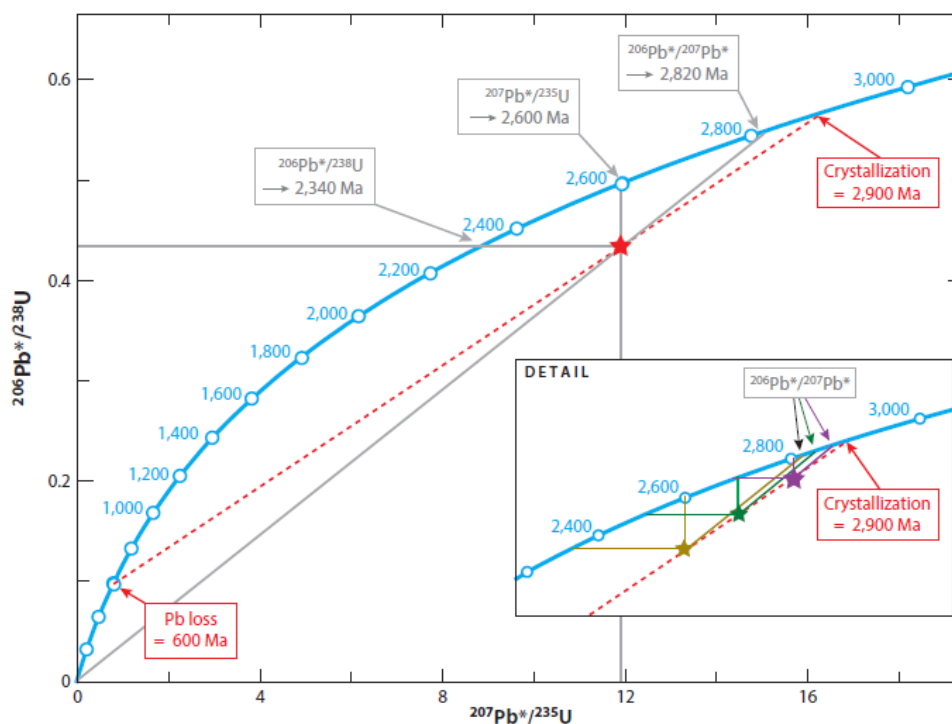

Figura 12. Exemplo de idade discordante em um diagrama Concórdia U/Pb, onde U^{235}/Pb^{207} (eixo x), U^{238}/Pb^{206} (eixo y) e Pb^{206}/Pb^{207} (diagonal) possuem valores diferentes (2340, 2600 e 2820 Ma). Em detalhe, três amostras discordantes ilustrando que o efeito da discordância é menor sobre a idade Pb^{206}/Pb^{207} (Fonte: Gehrels, 2014).

No caso de idades concordantes a escolha da razão a ser utilizada é baseada na precisão analítica que varia de tal forma que, $^{206}Pb/^{238}U$ é mais precisa para $t < 1,2$ Ga e $^{206}Pb/^{207}Pb$ é mais precisa para análises onde $t > 1,2$ Ga. A razão $^{207}Pb/^{235}U$ sempre possui maior incerteza do que as razões $^{206}Pb/^{238}U$ e $^{206}Pb/^{207}Pb$ e raramente é informada como a idade preferida. A única exceção para que a idade $^{207}Pb/^{235}U$ seja usada é no caso de zircões muito jovens, em que a idade $^{206}Pb/^{238}U$ é comprometida pelo decaimento do Th (Schärer, 1984).

2.4.2. Isótopos estáveis de oxigênio e o fracionamento isotópico

Os primeiros trabalhos que remetem ao estudo de isótopos de oxigênio em rochas são oriundos da década de 50 e 60, a exemplos dos trabalhos de Baertschi (1950) e Taylor (1968). Um dos principais aspectos positivos para o uso de isótopos estáveis de oxigênio, encontra-se no fato deste elemento estar presente na estrutura da grande maioria dos minerais, e desta forma possibilitar o emprego da técnica em variadas litologias, através do estudo de diversos minerais como, por exemplo,

quartzo, granada, olivina e, principalmente, zircão. A grande vantagem do uso do zircão, segundo Valley (2003), é que os cristais de zircão, quando não metamórficos, preservam a assinatura isotópica de oxigênio do momento da sua cristalização, mesmo quando submetidos a metamorfismo de alto grau; e, portanto, essa assinatura pode ser correlacionada com a idade U-Pb e a composição de elementos traço deste mineral. Além disso, a assinatura isotópica de oxigênio do evento metamórfico pode ser preservada nas bordas dos cristais de zircão, sem afetar a assinatura ígnea preservado no núcleo de cristais zonados (Scherer; Peck et al. (2003).

A simbologia comumente utilizada para se referir a valores de isótopos de oxigênio é $\delta^{18}\text{O}$, a qual é descrita por Garlick (1966), de forma que:

$$\delta^{18}\text{O} = \left[\frac{\frac{^{18}\text{O}}{^{16}\text{O}} \text{ medido no mineral}^*}{\frac{^{18}\text{O}}{^{16}\text{O}} \text{ VSMOW}^{**}} - 1 \right] 1000 \quad \text{Equação 22}$$

* ou rocha total.

** do inglês *Vienna Standard Mean Ocean Water* (VSMOW).

SMOW é a abreviação da sigla *Standard Mean Ocean Water* que representa a razão isotópica natural medida na água oceânica. *Vienna Standard Mean Ocean Water* (VSMOW) é um padrão desenvolvido em laboratório por Craig (1961) de maneira que as razões isotópicas de oxigênio e hidrogênio fossem as mesmas das medidas naturalmente no SMOW. O padrão VSMOW possui, de fato, a mesma razão de $^{18}\text{O}/^{16}\text{O}$ do valor natural SMOW, enquanto a razão de $^2\text{H}/^1\text{H}$ é 0.2‰ menor do que no SMOW, o que, no entanto, fica dentro da margem de erro das medidas laboratoriais (International Atomic Energy Agency, 2009). A razão isotópica $^{18}\text{O}/^{16}\text{O}$ medida no padrão VSMOW é $0,00200520 \pm 0,00000045$ (International Atomic Energy Agency, 2009) enquanto as demais razões isotópicas são mostradas na tabela 3.

Tabela 3. Razões de abundância isotópica absoluta de isótopos de hidrogênio e oxigênio medidas no padrão VSMOW (Fonte: International Atomic Energy Agency, 2009).

	Razão Isotópica	Incerteza	Método
$^2\text{H}/^1\text{H}$	0,00015576	0,00000005	Espectometria de massa
$^2\text{H}/^1\text{H}$	0,00015575	0,00000008	Espectometria de massa
$^2\text{H}/^1\text{H}$	0,00015560	0,00000012	<i>Fourier-Transform Nuclear Magnetic Resonance</i>
$^{18}\text{O}/^{16}\text{O}$	0,00200520	0,00000045	Espectometria de massa
$^{17}\text{O}/^{16}\text{O}$	0,00037990	0,00000080	Espectometria de massa

A equação 22 prediz que: i) se $\frac{^{18}\text{O}}{^{16}\text{O}}$ medido no mineral = $\frac{^{18}\text{O}}{^{16}\text{O}}$ VSMOW, logo $\delta^{18}\text{O}=0$; ii) se $\frac{^{18}\text{O}}{^{16}\text{O}}$ medido no mineral $> \frac{^{18}\text{O}}{^{16}\text{O}}$ VSMOW, logo $\delta^{18}\text{O} > 0$; e iii) se $\frac{^{18}\text{O}}{^{16}\text{O}}$ medido no mineral $< \frac{^{18}\text{O}}{^{16}\text{O}}$ VSMOW, logo $\delta^{18}\text{O} < 0$. Assim, quanto mais positivo o valor de $\delta^{18}\text{O}$ for, mais enriquecido no isótopo pesado (^{18}O) o material/mineral será, e quanto menor o $\delta^{18}\text{O}$, mais empobrecido (*depleted*) em ^{18}O . O enriquecimento/empobrecimento dos isótopos estáveis pesados em relação aos isótopos estáveis leves se dá devido ao “fracionamento isotópico”.

O fracionamento isotópico entre duas fases (mineral ou rocha) é, segundo Garlick (1966), representado pela diferença do valor de $\delta^{18}\text{O}$ registrado entre essas fases. O fracionamento de isótopos estáveis para diversos minerais foi estimado através de experimentos, medidas empíricas em amostras naturais e cálculos teóricos baseados em espectroscopia e potencial eletrostático (Valley, 2003). Desta forma, a partir de todos esses estudos combinados, pode-se estabelecer uma equação de fracionamento global que prediz o fracionamento isotópico de um elemento para um mineral em temperaturas acima de 600 °C (Matthews et al., 1983; Valley, 2003):

$$\delta^{18}\text{O}_A - \delta^{18}\text{O}_B =$$

$$\Delta_{A-B} \approx 1000 \ln(\alpha_{A-B}) = \text{Equação 23}$$

$$A_{A-B} \cdot 10^6 / T^2$$

Onde A_{A-B} é o coeficiente de fracionamento entre as fases “A” e “B” e T é a temperatura, expressa em Kelvin. Como cada mineral possui um valor específico para o coeficiente A_{A-B} da equação 23, é possível calcular o fracionamento de um elemento

químico entre duas fases minerais diferentes. A tabela 4 resume os valores do coeficiente A_{A-B} do oxigênio para os minerais mais estudados, inclusive o zircão. A figura 13, por sua vez, demonstra os valores típicos de $\delta^{18}\text{O}$ para diferentes materiais naturais.

Tabela 4. Fracionamento de isótopos de oxigênio entre os minerais mais estudados (Fonte: Valley, 2003).

No entanto, Valley (2003) destaca que o coeficiente A, na equação 23, assume a expressão $1000 \ln(\alpha_{A-B})$ vs. $1/T^2$ como linear, o que, segundo esse autor, nem sempre é observado a baixas temperaturas, e por isso, esses coeficientes devem ser aplicados apenas em casos onde a temperatura é maior que 600 °C, como mencionado anteriormente. A aplicação da equação para temperaturas menores que 600 °C é discutida por Chacko et al. (2001). Segundo esses autores, acima de 600 °C o fracionamento isotópico de oxigênio entre os minerais anidros é aproximadamente lineares a partir da origem, quando representados em relação a $1/T^2$ (a exemplo da equação 23). No entanto, abaixo de 600 °C, algumas curvas de fracionamento mineral-mineral se tornam significativamente mais complexas e extrapolações lineares dessas curvas podem resultar em cálculos errôneos de fracionamento, especialmente em temperaturas abaixo de 400 °C. Para casos de T menores que 100 °C o fracionamento entre dois minerais geralmente varia linearmente em relação $1/T^1$ e não mais $1/T^2$ (Chacko et al., 2001). Dessa forma, uma vez que T está no

denominador da equação, isso significa que o fracionamento isotópico é intensificado a baixas temperaturas.

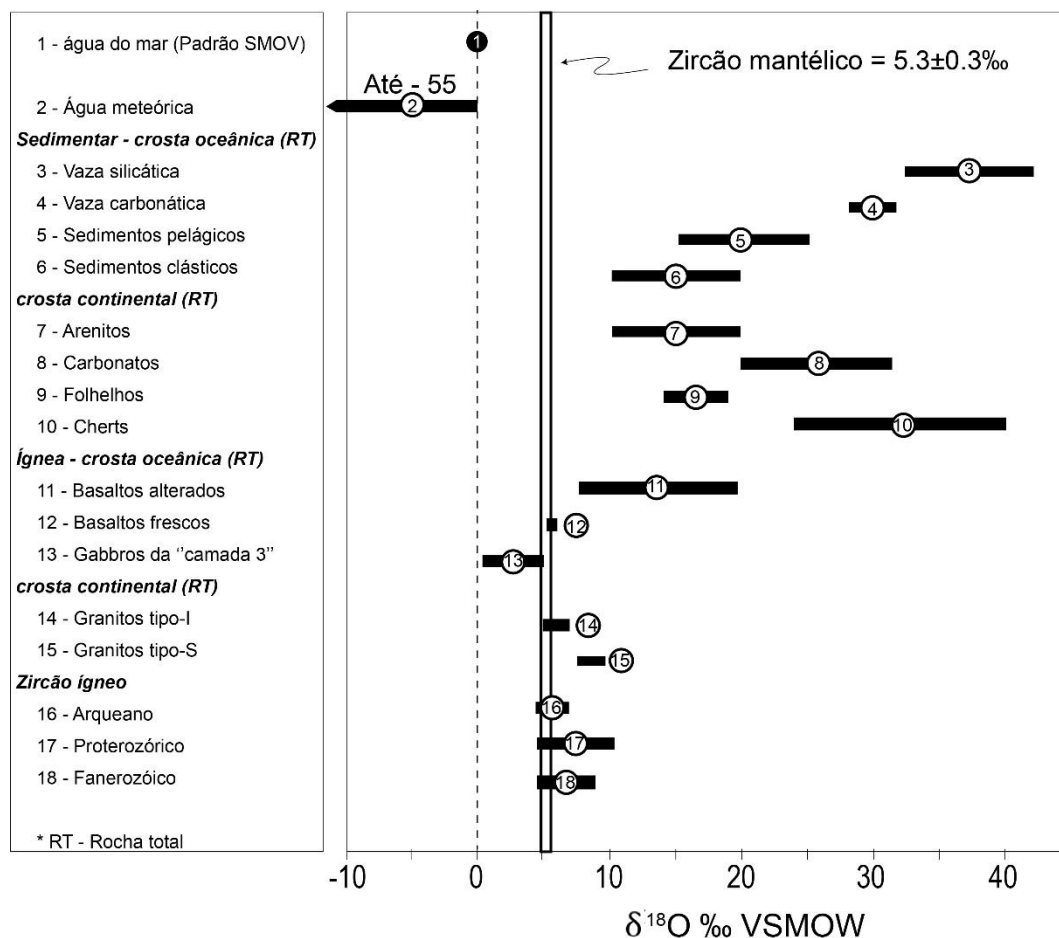

Figura 13. Valores típicos de $\delta^{18}\text{O}$ para diferentes rochas e minerais; além da água do mar (padrão VSMOW, ou seja, $\delta^{18}\text{O}=0$) e água meteórica (Fonte: Modificado de Eiler, 2001; e Valley et al., 2005).

Em se tratando do mineral zircão, a relação entre o valor de $\delta^{18}\text{O}$ deste em comparação ao $\delta^{18}\text{O}$ da rocha total em que ele se encontra, ou seja, o fracionamento entre essas duas fases ($\Delta^{18}\text{O}_{(\text{Zrc}-\text{RT})}$), dependerá da mineralogia da rocha. Em condições de temperatura magmática este fracionamento ($\Delta^{18}\text{O}_{(\text{Zrc}-\text{RT})}$) é uma função aproximadamente linear a porcentagem de peso de SiO_2 da rocha (wt. % SiO_2) (Valley et al., 2005). O fracionamento entre zircão e rocha total varia de $\delta^{18}\text{O} \sim 0.5\text{‰}$ em rochas máficas e $\sim 2\text{‰}$ em rochas félsicas, de acordo com a relação (Valley et al., 1994):

$$\Delta^{18}\text{O}_{(\text{Zrc}-\text{RT})} = \delta^{18}\text{O}_{(\text{Zrc})} - \delta^{18}\text{O}_{(\text{RT})} \approx -0.0612(\text{wt. \% SiO}_2) + 2.5 \quad \text{Equação 24}$$

O motivo do fracionamento entre o $\delta^{18}\text{O}$ do zircão e o $\delta^{18}\text{O}$ da rocha total variar com o teor de sílica será abordado mais profundamente no item 2.4.4, onde é discutido sobre como os processos geológicos influenciam o $\delta^{18}\text{O}$ de rochas e minerais.

2.4.3. Taxa de difusão e temperatura de fechamento nos estudos de geocronologia

A taxa de difusão é um parâmetro crucial em estudos isotópicos, pois é ela determinará a velocidade com que um elemento químico será trocado entre o mineral e o meio em que ele se encontra. Esta propriedade é comumente modelada levando em conta todo o volume de um cristal, simulando um fluxo normal de um elemento iniciado na borda e indo em direção ao centro do grão (Valley, 2003). A taxa de difusão de cada elemento químico em um mineral específico é bastante variável, uma vez que depende das propriedades químicas e físicas de ambos. No zircão, em temperaturas de 1100°C o Pb radiogênico possui taxa de difusão quatro ordens de magnitude maior do que os elementos radioativos Th e U (Lee et al., 1997).

A difusão é também um importante mecanismo de troca de oxigênio em diversos minerais, como destacado por Cherniak & Watson (2001), Peck et al. (2003), Watson & Cherniak (1997) e outros autores. A taxa de difusão do oxigênio nos cristais de zircão é, no entanto, baixa sob altas temperaturas (Watson & Cherniak, 1997; Peck et al., 2003). Porém, vários estudos demonstram que o coeficiente de difusão de oxigênio no zircão varia com a presença ou ausência de água - com $\text{P}_{\text{H}_2\text{O}}$ ou sem $\text{P}_{\text{H}_2\text{O}}$ (Watson & Cherniak, 1997). Valley (2003) destaca que outras variáveis, incluindo recristalização, sobrecrescimentos, precipitação de material ao longo de microfraturas, além de inclusões, defeitos cristalinos e traços de fissão também podem alterar o $\delta^{18}\text{O}$ do zircão e causar heterogeneidades dentro de um mesmo cristal.

Na tentativa de melhor entender a difusão de oxigênio em diferentes minerais, Peck et al. (2003) e Valley et al. (1994) avaliaram o comportamento do oxigênio para três diferentes minerais de uma mesma rocha: quartzo, granada e zircão. Os autores demonstraram que o $\delta^{18}\text{O}$ de minerais como quartzo e granada são reequilibrados quando submetidos a um evento metamórfico de alto grau, ao passo que o zircão não sofre reequilíbrio e mantém seu valor magmático original. Dessa forma, nesse exemplo, a difusão de oxigênio, sob as condições acima citadas, é ativa e eficiente no quartzo e granada, porém não para zircão. Ainda, Peck et al. (2003) demonstraram a existência de uma borda formada por difusão nos cristais de zircão metamorfizados a

cerca de 675°C. O valor de $\delta^{18}\text{O}$ da borda destes cristais foram maiores que os medidos no núcleo, pois, segundo os autores, os núcleos preservam o valor de $\delta^{18}\text{O}$ do evento magmático, devido à baixa taxa de difusão do oxigênio nos cristais de zircão. Esse exemplo é uma demonstração de outra variável que controla a taxa de difusão de um cristal: o seu tamanho (Watson & Cherniak, 1997). Uma vez que a taxa de difusão é dependente do volume, cristais menores são mais comumente totalmente reequilibrados do que os de maiores dimensões. Os cristais maiores, por sua vez, podem reequilibrar apenas suas bordas e manter seus núcleos preservados.

A temperatura em que a difusão de um determinado elemento no interior do cristal cessa é conhecida como “temperatura de fechamento”. É importante destacar que, assim como a taxa de difusão, a temperatura de fechamento é variável para diferentes elementos químicos de um mesmo mineral. No zircão, a temperatura de fechamento do Pb é superior a 900°C, enquanto para U e Th a difusão deixa de ser efetiva a 1100 °C (Lee et al., 1997). Dessa forma, Lee et al. (1997) concluem que a temperatura de fechamento do sistema U-Th-Pb se dá a 900°C no zircão, quando a difusão do chumbo deixa de ser efetiva. Alguns estudos corroboram com essa afirmativa e demonstram que o sistema U-Th-Pb se mantém fechado sob altas temperaturas em metamorfismo de alto grau (e.g. Maidment et al. 2013), no entanto, outros autores argumentam que esse sistema pode ser parcialmente afetado nessas condições (e.g. Wan et al., 2011). A temperatura de fechamento do zircão para os isótopos de oxigênio é incerta (Watson & Cherniak, 1997). Em situações onde a água não está presente, em um magma sob resfriamento lento, a temperatura de fechamento do zircão para oxigênio pode ser superior a 900°C (Watson & Cherniak, 1997), ao passo que, a adição de água no sistema, torna a difusão bem mais eficiente. Segundo estimativas dos mesmos autores, usando $P_{\text{H}_2\text{O}} = 70$ bar, a temperatura de fechamento do zircão para a difusão de oxigênio é em torno de 500-550 °C.

2.4.4. $\delta^{18}\text{O}$ do zircão mantélico e os processos geológicos modificadores do $\delta^{18}\text{O}$ dos minerais

O valor de $\delta^{18}\text{O}$ padrão para zircões cristalizados em equilíbrio com as altas temperaturas do manto foi estabelecido por Valley et al., (1998). Os valores de δO_{18} provindos de análises de zircão em um kimberlito se situam estaticamente em $5.3 \pm 0.3\text{‰}$ (1 σ - Valley et al., 1998) (Fig. 14A). No entanto, Valley et al., (1998) e Eiler (2001), entre outros autores, destacam que o valor de $\delta^{18}\text{O}$ do manto seja

possivelmente heterogêneo e complexo, e amostras ocasionais podem apresentar variações (Fig. 14B).

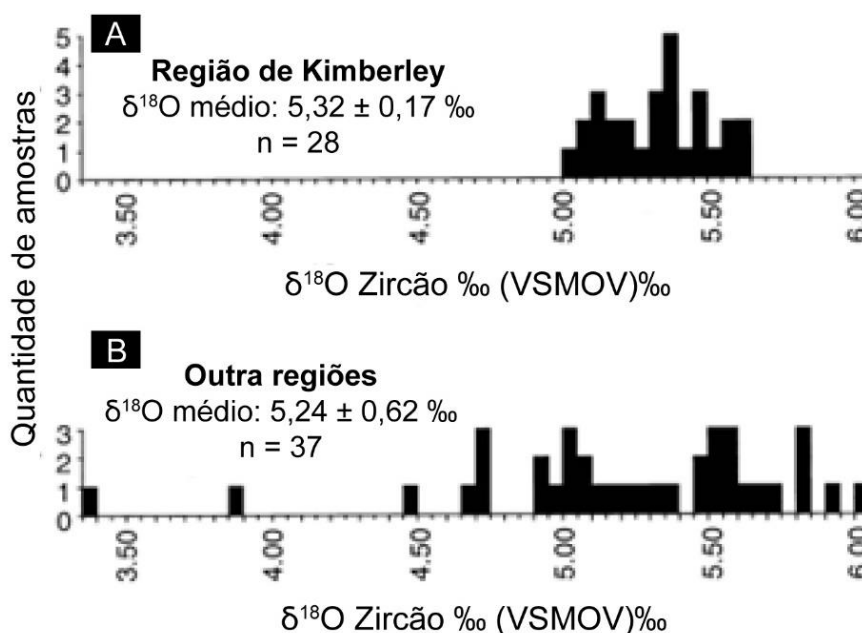

Figura 14. Valores $\delta^{18}\text{O}$ medidos em zircão de rochas máficas e ultramáficas. A) megacristais da região de Kimberley; e B) outras amostras de diferentes regiões do mundo (Fonte: modificado de Valley, 2003).

Os isótopos de oxigênio são importantes aliados na elucidação de processos atuantes durante a evolução de um magma (Eiler, 2001; Valley et al., 2005; Scherer et al., 2007), sendo que, no caso do zircão, um único grão pode registrar mais de um processo, que são comumente marcados por suas zonações ou intercrescimentos (Peck et al., 2003; Scherer et al., 2007). O registro desses processos pode auxiliar, por exemplo, para diferenciar um magma que evoluiu por cristalização fracionada, de outro que teve assimilações, ou aporte. Segundo Valley (2003), se um conjunto de magmas máficos e félsicos, em um sistema fechado, diferenciar por cristalização fracionada a partir de um magma parental, os valores de $\delta^{18}\text{O}$ dos cristais de zircão em todas as rochas dessa série serão os mesmos, mesmo que o valor de $\delta^{18}\text{O}$ de rocha total do magma félsico seja 1-2 ‰ maior do que o da rocha máfica, dada pela relação da equação 24. Isso ocorre porque todas as fases são consideradas em equilíbrio durante todo o processo e a diferenciação progride pela remoção precoce dos minerais máficos, os quais possuem menores valores de $\delta^{18}\text{O}$ em comparação com o quartzo e o feldspato, concentrados nos membros finais félsicos. Desta forma, o valor de $\delta^{18}\text{O}$ total da rocha félsica será maior pelo fato de esta possuir maior proporção de minerais enriquecidos em $\delta^{18}\text{O}$ (como quartzo e feldspato), mas o valor

de $\delta^{18}\text{O}$ de cada fase mineral individual será igual no membro máfico ou félsico da série. A figura 15 exemplifica essa questão, onde cristais de zircão com mesmo $\delta^{18}\text{O}$ são encontrados em rochas com diferentes teores de sílica de uma série magmática .

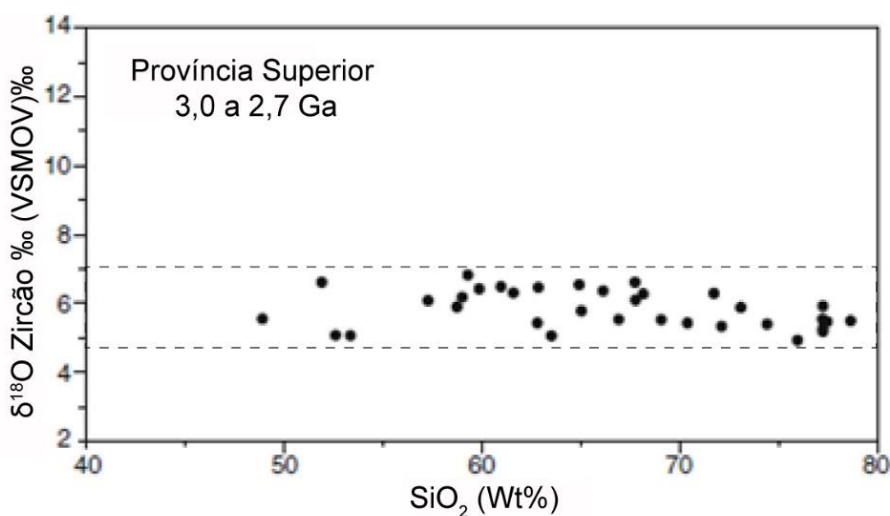

Figura 15. $\delta^{18}\text{O}$ em zircão comparados ao conteúdo de sílica de 35 amostras da Província Superior, no Canadá. Note que o teor de $\delta^{18}\text{O}$ no zircão permanece similar, mesmo o teor de sílica sendo bastante variável. A maioria das amostras são tonalitos, trondhjemitos e granodioritos (TTG) e rochas vulcânicas associadas com $\delta^{18}\text{O}$ médio de 5.5 ± 0.7 (1 SD) (Fonte: modificado de Valley et al., 2005).

Em contrapartida, a assimilação de novos materiais por um magma também pode ser registrada. Se algum material é adicionado ao magma, e este material não esteja em equilíbrio isotópico, ou seja, possua um valor de $\delta^{18}\text{O}$ diferente do magma que o está absorvendo, então o $\delta^{18}\text{O}$ do magma será alterado, assim como o $\delta^{18}\text{O}$ dos minerais subsequentes cristalizados, incluindo o zircão (Peck et al., 2001; Valley et al., 2005; Kemp et al., 2006). Os processos mais comuns que caracterizam tal tipo de situação são o aporte de outros magmas, assimilação de encaixante e fusão crustal (Peck et al., 2001; Valley et al., 2005; Kemp et al., 2006).

Processos hidrotermais também são importantes modificadores nos valores de $\delta^{18}\text{O}$ dos minerais (Peck et al., 2001; Kemp et al., 2006). Tais fluidos possuem valores de $\delta^{18}\text{O}$ muito baixos, entre 0 e -55 (Eiler, 2001; Valley et al., 2005), e dessa forma, pode reduzir drasticamente os valores de $\delta^{18}\text{O}$ dos minerais, caso haja interação entre os dois meios. Os riolitos de baixo $\delta^{18}\text{O}$ de Yellowstone (Bindeman & Valley, 2000; Valley, 2003; Valley et al., 2005), são exemplos desse fenômeno. A geração destas rochas está relacionada a câmaras magmáticas sub-vulcânicas rasas cujas paredes foram hidrotermalizadas. Essas paredes então foram assimiladas durante a geração dos riolitos por atividade magmática explosiva e influíram nos valores de $\delta^{18}\text{O}$ dos

minerais cristalizados (Bindeman & Valley, 2000; Valley, 2003; Valley et al., 2005). Desta forma, os cristais de zircão destas rochas chegam a apresentar valores de $\delta^{18}\text{O}$ menores que 5 ‰, ou seja, menores que os valores mantélicos. Ainda, em cenários de rifte, casos onde o derretimento de gelo afetaram os valores de $\delta^{18}\text{O}$ de rochas subsequentemente recristalizadas também foram reportados (Wickham & Taylor, 1985).

Com o passar do tempo geológico os processos supracitados irão exercer enorme influência sobre os valores de $\delta^{18}\text{O}$ do zircão e demais minerais, principalmente em rochas que envolvam demasiados processos crustais. Sedimentos reciclados e outros materiais supra-crustais comumente têm $\delta^{18}\text{O}$ mais alto que o do zircão mantélico (Valley et al., 2005). Tal evolução é demonstrada e discutida, por exemplo, por Peck et al. (2001), Valley (2003) e principalmente Valley et al. (2005). O resultado da atuação desses processos é que os valores de $\delta^{18}\text{O}$ para zircão são muito mais uniformes para a primeira metade da história terrestre, e muito mais variados para os tempos geológicos mais jovens (Valley et al., 2005) (Fig. 16). Tais variações nos valores de $\delta^{18}\text{O}$ do zircão ocorrem, pois a subducção, bem como os ambientes sedimentares, se tornaram mais ativos desde o Proterozóico. Os ambientes sedimentares são importantes porque favorecem a atuação de processos de baixa temperatura, os quais são muito mais eficientes no fracionamento de $\delta^{18}\text{O}$ (Matthews et al., 1998). A subducção, por sua vez, é a responsável por levar esse material fracionado, além da crosta oceânica alterada, para o manto e gerar magmas com valores de $\delta^{18}\text{O}$ maiores (Simon & Lécuyer, 2005). Dessa forma, os isótopos de oxigênio de magmas com contaminação crustal refletem uma mistura em escala geológica do manto e da crosta (Valley, 2003).

Amostras do Arqueano, revelam que os zircões magmáticos dessa idade possuem $\delta^{18}\text{O}$ variando entre 5 e 7.5‰ (Valley, 2003; Valley et al., 2005), com um valor médio de $5.82 \pm 0.74\text{‰}$ (Valley et al., 2005) (Fig. 16). Os valores menores ($5.3 \pm 0.3\text{‰}$) refletem cristais de zircão em equilíbrio com as altas temperaturas do manto (Valley et al., 2005), ao passo que, os valores levemente mais evoluídos (6.5 a 7.5‰) são interpretados como resultado da fusão de protólitos que sofreram interação com águas superficiais a baixa temperatura, gerando magmas levemente enriquecidos (Peck et al., 2001). Durante o Proterozóico, o intervalo e os valores de $\delta^{18}\text{O}$ dos cristais de zircão aumentaram gradualmente em uma mudança secular que documenta a maturação da crosta (Valley et al., 2005). Rochas mais jovens que 2.5 Ga, sejam elas Proterozóicas ou Fanerozóicas, apresentam mais comumente zircão com valores de

$\delta^{18}\text{O}$ entre 8‰ a >10‰, enquanto o $\delta^{18}\text{O}$ da rocha total, nessas ocasiões, varia de 9‰ a maiores que 12‰.

Figura 16. Compilação $\delta^{18}\text{O}$ vs idade obtidos em zircão de mais de 1200 rochas. Valores no arqueano são muito mais uniformes e próximos do manto ($5,3 \pm 0,3\text{‰}$), enquanto, após 2,5 Ga, valores de $\delta^{18}\text{O}$ superiores a 7,5‰ são observados. Períodos de crescimento de supercontinentes são mostrados por barras na porção inferior: P - Pangeia; G - Gondwana; R - Rodinia. LTB - Bombardeio Tardio, CEE - Terra primitiva fria e O_2 - aumento de oxigênio na atmosfera (Fonte: modificado de Valley et al., 2005).

2.4.5. Discordância U-Pb e a relação com $\delta^{18}\text{O}$ no zircão

A interação da rocha com fluídos é um dos fatores mais comumente responsável pela perturbação da assinatura isotópica dos minerais, incluindo elementos como chumbo e oxigênio, além de muitos outros. Sabendo desse fator determinante, Booth et al. (2005) buscaram encontrar alguma possível correlação entre o grau de discordância das idades U-Pb e os valores de $\delta^{18}\text{O}$ dos cristais de zircão. O resultado dos autores foi que, para as amostras analisadas, o zircão apresentava três texturas diferentes: A, B e C (Fig. 17).

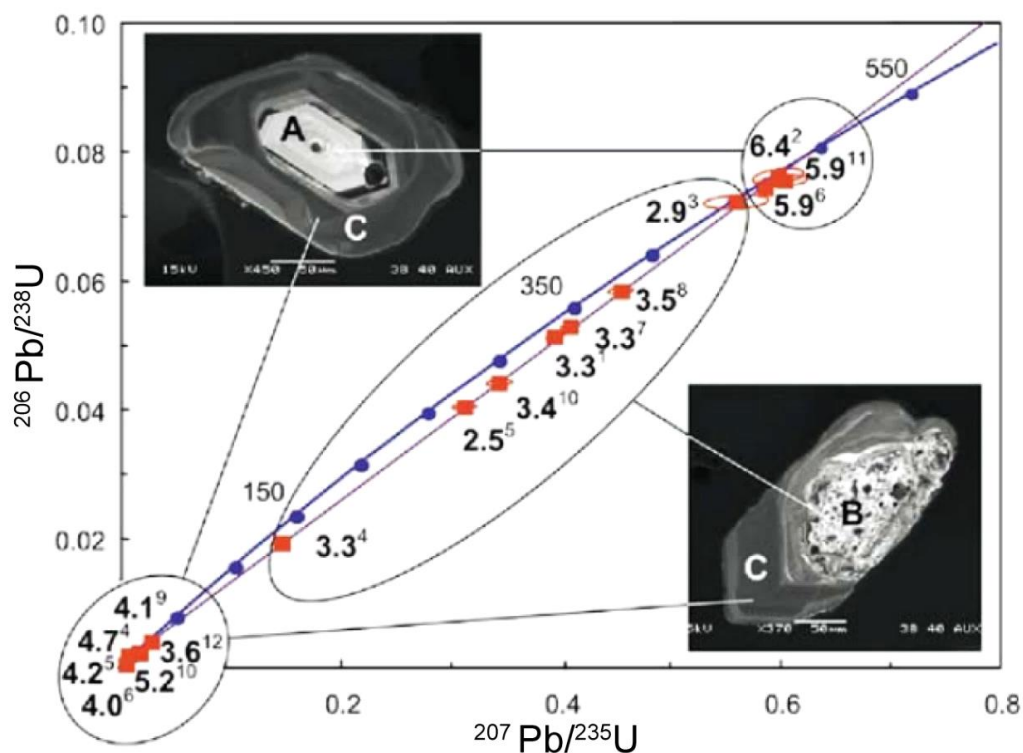

Figura 17. Diagrama concórdia U-Pb dos grãos analisados por Booth et al. (2005), em vermelho, com valores de $\delta^{18}\text{O}$ medidos, indicado em negrito. A textura representativa de cada grupo de grãos também é indicada (Fonte: Booth et al., 2005).

A textura “A” é caracterizada por cristais prismáticos, valores de $\delta^{18}\text{O}$ mais altos e idades concordantes, sendo a representante do magma original. A textura “B” apresenta cristais discordantes, com os menores valores de $\delta^{18}\text{O}$, e é resultado da recristalização por dissolução de núcleos ígneos de zircões em contato com fluídos de origem meteórica. A textura “C” apresenta valores de $\delta^{18}\text{O}$ intermediários entre “A” e “B”, e plota no intercepto inferior da curva discórdia, interpretada como um sobrecrescimento tardio nos núcleos preexistentes de zircão.

Booth et al. (2005) concluíram que os zircões que sofreram perturbações no U-Pb original são frequentemente também empobrecidos de forma variável em $\delta^{18}\text{O}$, mas a relação entre discordância na idade U-Pb e $\delta^{18}\text{O}$ não é sistemática. A redução em $\delta^{18}\text{O}$ não depende diretamente do grau de discordância; em vez disso, é uma função da acessibilidade de um dado zircão à solução aquosa (Booth et al., 2005).

3. Resumo dos resultados

Esta tese aborda uma discussão da relação espacial e temporal de três complexos metamórficos posicionados no setor central do Cinturão Dom Feliciano, no estado do Rio Grande do Sul, Brasil. Os novos dados de geocronologia, geoquímica elementar e isotópica, e modelamento de condições metamórficas permitiram aprofundar o conhecimento sobre os complexos Porongos, Várzea do Capivarita e Passo Feio. Estes novos dados, em conjunto com os dados da literatura, possibilitaram um avanço no entendimento da evolução geológica do Cinturão Dom Feliciano. Os resultados desta tese são apresentados na forma de três artigos científicos, cujas sínteses são descritas abaixo:

3.1. O ambiente vulcanosedimentar compartilhado pelos complexos Porongos e Várzea do Capivarita em ca. 800-770 Ma.

No primeiro artigo foi investigada a história pré-colisional do Cinturão Dom Feliciano (anterior a ca. 660 Ma) através do estudo de geocronologia e de isótopos de oxigênio em zircão nas rochas ortometamórficas intercaladas nas sequências metassedimentares do Complexo Várzea do Capivarita (CVC) e Complexo Porongos (CP). Duas amostras do Complexo Várzea do Capivarita e uma do Complexo Porongos foram investigadas. As idades de cristalização para o protólito ígneo (U–Pb em zircão) dos dois ortognaisses do CVC foram 786 ± 5 Ma (2σ) e 790 ± 7 Ma (2σ), respectivamente. Para o metariolito do CP a idade de cristalização obtida para o protólito ígneo foi de 787 ± 5 Ma (2σ).

O valor médio calculado para os isótopos de oxigênio (δO_{18}) nestes cristais de zircão de ca. 790 Ma foi de $8,41 \pm 0,13\%$ e $8,68 \pm 0,14\%$, para os ortognaisses do CVC, e $8,75 \pm 0,72\%$, para o metariolito do CP. Tais valores são maiores que os valores característicos de zircão mantélico ($5,3 \pm 0,3\%$) e sugerem que provavelmente esses cristais de zircão cristalizaram em magmas mais evoluídos, seja por fusão de rochas encaixantes ou de sedimentos (*i.e.* subducção) ou por assimilação de material crustal por magmas mantélicos, como por exemplo pelo processo de assimilação–cristalização fracionada.

Uma amostra adicional de paragnaisse pelítico foi analisada com o intuito de se estabelecer a idade deposicional do Complexo Várzea do Capivarita. A população detrítica majoritária desta amostra se concentra entre 790-750 Ma. Além disso, o

espalhamento das idades detríticas está centrado em ca. 790 Ma, que corresponde à idade de cristalização dos ortognaisses. Este dado sugere uma contemporaneidade entre essas amostras, ou que o protólito sedimentar é principalmente um produto da erosão das rochas magmáticas de 790 Ma. Tais hipóteses são corroboradas pelo valor similar de δO_{18} encontrado nos cristais de zircão neoproterozóicos do paragnaisse (8.03 ± 0.33). Assim, interpretamos que esses dados sugerem uma história sin-vulcanosedimentar para o paragnaisse amostrado e, portanto, uma história sin-vulcanosedimentar para, pelo menos, parte do Complexo Várzea do Capivarita. Além disso, a correspondência dos dados geocronológicos e dos valores de δO_{18} em zircão sugerem que as rochas ortometamórficas estudadas do Complexo Várzea do Capivarita e Complexo Porongos compartilharam a mesma história ígnea. Assim, tais amostras provavelmente representem parte de um mesmo evento magmático em diferentes níveis de uma única bacia sedimentar em ca. 800-770 Ma.

3.2. História deformacional polifásica do Cinturão Dom Feliciano registrada nos complexos Porongos e Passo Feio.

O segundo artigo da tese teve por objetivo investigar a história colisional do Cinturão Dom Feliciano no antepaís oeste da colisão, com enfoque nos Complexos Porongos e Passo Feio, os quais careciam de dados. O Cinturão Dom Feliciano é a parte sul-americana de um extenso sistema orogênico neoproterozóico que teve sua estrutura principal desenvolvida durante o final do criogeniano e o ediacarano. Nesse artigo, modelamentos termodinâmicos (estimativas P-T), geocronologia de Lu–Hf granada–rocha total e U–Pb *SIMS* em monazita, além de elementos traços em granada e monazita foram obtidos para duas amostras metassedimentares do Complexo Porongos e uma do Complexo Passo Feio. Tais dados permitiram novas interpretações sobre a evolução tectônica do Cinturão Dom Feliciano.

O estudo na região leste do Complexo Porongos permitiu estabelecer que o evento metamórfico principal ocorreu em 662 ± 13 Ma (isócrona Lu–Hf granada–rocha total) sob condições de pico metamórfico de ca. 560–580 °C e 5.8–6.3 kbar. Esse episódio metamórfico-deformacional representa um evento de espessamento crustal no antepaís do Dom Feliciano em resposta ao início da tectônica transpressiva convergente do cinturão. Os cristais de monazita estudados de idade 614 ± 6 Ma (U–Pb *SIMS*) são interpretados como tendo sua gênese associada a fluídos oriundos da

atividade magmática nas proximidades, pós-exumação, e sugerem que a região leste do Complexo Porongos foi exumada em algum momento entre ca. 660 e 615 Ma.

O estudo de uma amostra da região oeste do Complexo Porongos permitiu estabelecer que o principal evento metamórfico-deformacional dessa região ocorreu em condições de 550–570°C e 4.5–5.5 kbar durante ca. 563 ± 12 Ma (isócrona Lu–Hf granada–rocha total). A exumação desta parte do antepaís é datada pela cristalização de monazita durante a quebra da granada e sugere retrometamorfismo em 541 ± 7 Ma (U–Pb *SIMS*). No Complexo Passo Feio, à oeste, a xistosidade metamórfica principal se desenvolveu durante 571 ± 13 Ma (isócrona Lu–Hf granada–rocha total) em condições de pico metamórfico de 560–580 °C e 4.7–6.4 kbar.

Os novos dados de geocronologia e modelamento termodinâmico demonstram que a região oeste do Complexo Porongos e o Complexo Passo Feio foram deformados em condições PT e gradientes geotérmicos similares em ca. 560-570 Ma. Esse episódio metamórfico-deformacional representa um segundo evento de espessamento crustal no antepaís do Dom Feliciano e registra uma migração para oeste da frente orogênica em um sistema orogênico transpressivo de longa duração (ca. 660–560 Ma).

3.3. Caracterização dos diferentes magmatismos registrados nas sequências metamórficas dos complexos Porongos, Passo Feio e Várzea do Capivarita.

O terceiro artigo da tese teve por objetivo investigar o magmatismo intermediário a ácido que ocorre intercalado nas sequências metassedimentares dos complexos Porongos, Passo Feio e Várzea do Capivarita, com intuito de explorar mais a fundo as relações entre esses três complexos. Assim, dados de geoquímica elementar e de isótopos de Sr-Nd foram compilados da literatura para as rochas ortomemamórficas desses complexos. Tal abordagem foi escolhida, uma vez que as assinaturas geoquímicas e isotópicas são ferramentas importantes para a investigação de fontes magmáticas e, quando aliadas a outras ferramentas (*p.e.* geologia estrutural, geocronologia), podem ser utilizadas para ajudar na reconstrução dos ambientes geológicos originais.

Além dos dados compilados da literatura, novos dados de geoquímica elementar e isotópica são apresentadas para sete rochas metavulcânicas dos complexos Porongos e Passo Feio, entre as quais, duas foram selecionadas para análises U-Pb

por LA-ICPMS em zircão. O conjunto de dados foi comparado e agrupado em padrões geoquímicos a partir da investigação dos elementos maiores e traços. O aspecto que mais realça a separação dos grupos geoquímicos são os padrões de Elementos Terras Raras (ETRs): i) O grupo 1 apresenta um enriquecimento de ETRL (leves) em relação aos ETRP (pesados) ($\text{LaN/YbN} \approx 10$) e possui marcante anomalia negativa de Eu ($\text{Eu/Eu}^* = 0.38$ a 0.86); ii) O grupo 2 não possui anomalia de Eu ($\text{Eu/Eu}^* = 0.94$ a 1.07) e possui um enriquecimento mais pronunciado de ETRL em relação aos ETRP do que o grupo 1 ($\text{LaN/YbN} = 12$ a 44) e; iii) o grupo 3, que possui anomalia negativa de Eu ($\text{Eu/Eu}^* \approx 0.70$), porém dispõem de valores absolutos de ETRL muito maiores que os demais grupos ($\text{LaN/YbN} \approx 22$). Uma amostra metavulcânica básica, referida como *Bmvc*, apresenta um quarto padrão geoquímico. Embora o padrão de ETRs se aproxime ao das amostras do grupo 2, os demais elementos traços demonstram que *Bmvc* não pertence a nenhum dos três grupos pré-estabelecidos. Os novos dados de U-Pb em zircão para duas amostras metavulcânicas ácidas da região norte do Complexo Passo Feio forneceram idades de cristalização para o protólito ígneo em $\text{ca. } 580 \pm 2 \text{ Ma}$ (2σ).

Desta forma o magmatismo registrado pelas rochas ortometamórficas dos três complexos estudados pode ser agrupado em dois eventos magmáticos diacrônicos. As amostras do grupo geoquímico 1 fazem parte do primeiro evento magmático, o qual ocorreu em $\text{ca. } 810\text{--}780 \text{ Ma}$ no Complexo Várzea do Capivarita e na sequência Cerro da Árvore do Complexo Porongos. As rochas desse magmatismo representam uma associação magmática produzida por fontes relacionadas a subducção, e com significativa contribuição de materiais crustais, como indicado pelos dados de elementos maiores e traços e pelos valores isotópicos de $^{87}\text{Sr}/^{86}\text{Sr}_{(790 \text{ Ma})} > 0.715$ e $\epsilon\text{Nd}_{(790 \text{ Ma})}$ de -5 e -11 (até -22). Tais características são plausíveis para um ambiente de arco magmático maduro, que é o ambiente sugerido para esse magmatismo toniano. Os grupos 2, 3 e *Bmvc* fazem parte do segundo evento magmático, que ocorreu em $\text{ca. } 600\text{--}580 \text{ Ma}$ no Complexo Passo Feio, e na sequência Capané, situada na região oeste do Complexo Porongos. As amostras do grupo 2 e 3, por sua vez, são interpretadas como tendo fonte oriunda de um manto enriquecido por subducção, porém sem contribuição elevada de materiais crustais, conforme indicado pelos valores de $^{87}\text{Sr}/^{86}\text{Sr}_{(580 \text{ Ma})} = 0.7035\text{--}0.7050$ e $\epsilon\text{Nd}_{(580 \text{ Ma})} > -10$. Tais feições são passíveis de um ambiente de retro-arco, que é o ambiente sugerido para esse magmatismo. Para o padrão *Bmvc*, os dados sugerem uma origem mantélica sem enriquecimento por subducção e possivelmente indica fontes múltiplas para esse

magmatismo ediacarano recém-descoberto, e ainda, não completamente caracterizado.

A comparação dos dados da literatura com os novos dados apresentados, permitem uma nova interpretação quanto a evolução dos complexos Passo Feio e Porongos. Uma evolução geológica compartilhada é sugerida para o período de ca. 600–580 Ma entre os complexos Passo Feio e a sequência Capané, situada na região oeste do Complexo Porongos. Os dados também corroboram uma evolução compartilhada em ca. 810–770 Ma entre o Complexo Várzea do Capivarita e a sequência Cerro da Árvore do Complexo Porongos, como sugerido por outros autores.

4. Considerações Finais

A presente tese delimita alguns novos entendimentos sobre o Cinturão Dom Feliciano e como decorrência do avanço do conhecimento, abre espaço para novos questionamentos. A hipótese de correlação entre os complexos Várzea do Capivarita (CVC) e Porongos (CP) foi levantada a priori no trabalho de Martil (2016), quando esta autora demonstrou que a idade de cristalização dos ortognaisses do CVC eram semelhantes às idades das rochas metavulcânicas do CP (Saalman et al., 2011; Pertille et al., 2017). Martil et al. (2017) e Battisti et al. (2018) exploraram mais essa relação através da comparação geoquímica de CVC e CP e, no caso de Martil et al. (2017), também de isótopos de Sr-Nd. Martil et al. (2017) compararam dados de Sr-Nd de diversas amostras do CVC com uma amostra metavulcânica ácida do CP. Além disso, Battisti et al. (2018) demonstraram uma evolução estrutural bastante semelhante entre a região leste do CP e o CVC (estudado por Martil, 2016). Os dados de ambos os autores indicaram deformação progressiva em ambos os complexos, a qual se iniciou com a movimentação de zonas de cisalhamento sub-horizontais de vergência para oeste e evoluiu para zonas de transcorrência subverticais. No entanto, as rochas do CP comparadas quimicamente com o CVC por Battisti et al. (2018) não possuíam idade de protólito conhecida. Além disso, dados de Sr-Nd de apenas uma amostra metavulcânica do CP fora comparada com o CVC por Martil et al. (2017) e, portanto, mais dados eram necessários para confirmar essa relação. No artigo 1 desta tese, demonstramos que as rochas ortometamórficas dos complexos Várzea do Capivarita e Porongos comparadas por Martil et al. (2017) e Battisti et al. (2018), respectivamente, apresentam a mesma idade de cristalização para o protólito ígneo: ca. 790 Ma. Além disso, a assinatura isotópica de oxigênio entre o zircão de todas

essas amostras é inteiramente similar, o que sugere a mesma fonte ígnea para tais rochas. Tal semelhança entre as rochas ortometamórficas destes complexos é corroborada ainda pelos novos dados de Sr-Nd apresentados no artigo 3. Assim a conexão entre o magmatismo de ca. 790 Ma no período pré-colisional do além-país (ou *hinterland*), representado pelo CVC, e do ante-país (ou *foreland*), representado pelo CP, no setor central do Cinturão Dom Feliciano é demonstrada nessa tese.

No entanto, embora a correlação entre as rochas ortoderivadas do CP e CVC possa ser feita de maneira mais direta, a correlação entre as rochas metassedimentares desses complexos exige mais cautela. Tal assertiva provém da disparidade de estudos no CP e no CVC, sendo o primeiro mais bem estudado. Apesar disso, no entanto, a julgar pelos dados disponíveis, o intervalo de proveniência para as rochas pré-colisionais de ambos complexos é bastante similar: 750 Ma – 3.0 Ga, com picos em 1.2–1.5 e 2.0–2.3 Ga no CP (Gruber et al., 2016a; Pertille et al., 2017; Höfig et al., 2018); e 730 Ma – 2.5 Ga com picos de 1.9–2.2 Ga no CVC (Gruber et al., 2016b). O artigo 1 desta tese, no entanto, apresenta um caráter vulcanosedimentar para o CVC em ca. 790 Ma, com proveniência característica de bacias de ante-arco ou retro-arco (Cawood et al., 2012). Tal padrão difere do padrão de sedimentação típico de rifte registrado para o Complexo Porongos e sua continuação no Dom Feliciano norte (Complexo Brusque), como discutido por Percival et al. (2021). A correlação entre os complexos Várzea do Capivarita e Porongos durante o período pré-colisional do Cinturão Dom Feliciano parece ser cada vez mais clara, no entanto, o ambiente original de sua formação ainda é ambíguo, uma vez que a geoquímica elementar aponta para um ambiente de arco maduro (Martil et al., 2017; Battisti et al., 2018, De Toni et al., 2020b, essa tese) e a sedimentação tem um caráter de rifte, em sua maioria (Konopásek et al., 2020; Percival et al., 2021). Mais estudos de proveniência no Complexo Várzea do Capivarita são necessários e talvez ajudem a responder essa questão.

Por sua vez, a relação entre os complexos Porongos e Passo Feio parece estar relacionada ao período tardi-colisional, ligeiramente anterior ao segundo (e último?) evento de espessamento crustal na porção central do Cinturão Dom Feliciano, em ca. 565 Ma. Magmatismo de ca. 600–580 Ma é registrado, tanto na porção oeste do Complexo Porongos quanto no Complexo Passo Feio (CPF). Os dados de geoquímica indicam que esse magmatismo é complexo, uma vez que três padrões distintos foram delimitados, podendo inclusive se tratar de diferentes eventos magmáticos sincrônicos, no entanto, com fontes similares, conforme indicam os novos dados de

Sr-Nd. Um estudo de maior detalhe, com maior número de amostras é necessário para uma melhor caracterização desse magmatismo. O espaço de colocação dessas rochas magmáticas (agora metamórficas) também precisa ser detalhado, uma vez que suas assinaturas isotópicas indicam pouco retrabalhamento crustal, mesmo que sua colocação se disponha temporalmente entre dois eventos contracionais de espessamento crustal (em ca. 660 Ma e ca. 565 Ma). A pouca contaminação crustal sugere um magmatismo possivelmente em um ambiente de crosta atenuada. Conforme mostrado no artigo 3 dessa tese, dados de geoquímica e Sr-Nd sugerem que as rochas metavulcânicas de ca. 600–580 Ma intercaladas no complexo Passo Feio e Porongos possam ter sido geradas em um ambiente de retro-arco extensional, similar ao observado para o Grupo Maricá na Bacia do Camaquã que se desenvolveu em 630–600 Ma, na vizinhança do CP e do CPF (Borba et al., 2008; Almeida et al., 2012; Paim et al., 2014). Ainda, é possível sugerir a colocação desse magmatismo em bacias transtrativas resultantes da movimentação de zonas transcorrentes, similar ao observado no Grupo Bom Jardim da Bacia do Camaquã que se depositou entre 595–580 (Janikian et al., 2008, 2012). No entanto, como acima mencionado, ainda são necessários mais estudos, principalmente de geologia estrutural, para descrever com exatidão o ambiente dos complexos Porongos em Passo Feio em 600–580 Ma.

Além do magmatismo Ediacarano, uma conexão entre a região oeste do Complexo Porongos e o Complexo Passo Feio é indicada pelo metamorfismo contemporâneo (563 ± 12 vs 571 ± 13 Ma) em condições metamórficas inteiramente similares ($550\text{--}570^\circ\text{C}/4.5\text{--}5.5$ kbar vs $560\text{--}580^\circ\text{C}/4.7\text{--}6.4$ kbar), sob gradientes geotérmicos típicos de metamorfismo regional orogênico (25 to $35^\circ\text{C}/\text{km}$), conforme é demonstrado no artigo 2. A ocorrência desse segundo evento contracional está possivelmente associado a colisão tardia do Craton Kalahari com os crátons Río De la Plata e Congo, interpretado como responsável pela ativação de zonas transcorrentes em ca. 585 e ca. 550 Ma no Uruguai, por exemplo (Oriolo et al., 2016). É possível que a tectônica de baixo ângulo registrada no CPF e CP em ca. 565 Ma seja o registro de um componente compressivo ediacarano em resposta a partição da deformação dessas zonas de cisalhamento ativas no Uruguai, e que possivelmente se estenderam ao sul do Brasil. Sabe-se que a Zona de Cisalhamento de Caçapava do Sul, no limite leste do Complexo Passo Feio e oeste do Complexo Porongos, foi ativa durante a colocação do Granito Caçapava em 562 ± 8 Ma (Remus et al., 2000) e seria plausível que ela fora ativa anteriormente. No entanto, evidências para sugerir uma movimentação anterior a ca. 560 Ma ainda precisam ser levantadas.

Portanto, em suma, nessa tese uma conexão entre as evoluções dos complexos Porongos e Passo Feio também é sugerida. No entanto, adverte-se que para entender melhor essa relação, é necessário entender melhor o ambiente original de formação do Complexo Passo Feio e o espaço temporal no qual ele se desenvolveu. A temporalidade do complexo é pouco entendida, uma vez que existem poucos estudos de proveniência (Lopes et al., 2015; Souza, 2020; Philipp et al., 2021) e, anterior a esta tese, a idade do protólito das rochas metavulcânicas ácidas intercalados na sequência metamórfica era desconhecida. As rochas intermediárias e básicas conjuntamente intercaladas na sequência meta-vulcanossedimentar (Bitencourt, 1983) do Complexo Passo Feio também não dispõem de idades conhecidas.

Reconstitution of a volcano-sedimentary environment shared by the Porongos and Várzea do Capivarita Complexes at 790 Ma, Dom Feliciano Belt, southern Brazil

Dear Mr. Battisti,

We have received the above referenced manuscript you submitted to Precambrian Research.

To track the status of your manuscript, please log in as an author at <https://www.editorialmanager.com/precam/>, and navigate to the "Submissions Being Processed" folder.

Thank you for submitting your work to this journal.

Kind regards,
 Precambrian Research

ABSTRACT

This work investigates the pre-collisional (before ca. 650 Ma) history of the Dom Feliciano Belt in southernmost Brazil through geochronological and zircon oxygen isotope study. U–Pb SHRIMP dating of two orthogneiss samples from the Várzea do Capivarita Complex, and one metarhyolite sample from the Porongos Complex yielded crystallization ages of 786 ± 5 Ma, 790 ± 7 Ma and 787 ± 5 Ma, respectively. The mean oxygen isotopic values calculated for the ca. 790 Ma zircon cores from the orthogneisses yielded $8.41 \pm 0.13\text{‰}$ and $8.68 \pm 0.14\text{‰}$, and $8.75 \pm 0.72\text{‰}$ for the metarhyolite. Such values suggest that zircon crystallized in the more evolved magmas, either from melting of host rocks and sediments or assimilation of crustal material by mantle-derived magmas, as for example by assimilation-fractional crystallization process. Detrital zircon population was analysed in one additional paragneiss sample from the Várzea do Capivarita Complex, and most of the values cluster at 790–750 Ma. The spread of the data is centered at ca. 790 Ma, which is the crystallization age of the interleaved orthogneisses. In our interpretation, such dataset suggests a syn-volcanic origin of the paragneiss protolith, and therefore a volcano–sedimentary origin of the Várzea do Capivarita Complex. The correspondence of geochronological data and zircon oxygen isotope values for the studied meta-igneous samples suggests that the Várzea do Capivarita and Porongos complexes shared the same igneous history, and the samples probably represent a magmatic event at different levels of a single basin at ca. 800–770 Ma.

Keywords: *Pre-collisional setting, Volcanic-sedimentary origin, U-Pb zircon dating, Detrital zircon, Oxygen isotope in zircon*

1 **1. INTRODUCTION**

2
3 The original architecture of pre-collisional scenarios is difficult to reconstruct due
4 to the subsequent mountain-building processes (e.g. Cawood et al., 2009;
5 Vanderhaeghe, 2012; Chetty, 2017), including extensive deformation and
6 emplacement of post-orogenic magmatic rocks that mask the former pre-orogenic
7 relations. Thus, pre-orogenic basins commonly have their original stratigraphy
8 completely modified during deformation (Tavani et al., 2015; Lacombe & Bellahsen,
9 2016), disturbed also by contemporaneous high-grade metamorphism and partial
10 melting (Collins, 2002), and thrusting of the basement (Lacombe & Bellahsen, 2016).
11 Furthermore, in fold-and-thrust belts, as the case of the Dom Feliciano Belt in South
12 America, horizontal thrust sheets and shear-zones make the pre-orogenic
13 reconstitution even more difficult, as allochthonous sheets can be carried over
14 thousands of kilometres, often causing an inversion of the original stratigraphy and
15 higher-grade rocks are placed on top of lower grade ones, as can be observed in the
16 Himalayas, for instance (Harrison et al., 1999). Nevertheless, some approaches can
17 be chosen to address these problems despite the difficulty.

18 This paper provides an attempt to reconstruct the pre-orogenic scenario of the
19 Central Dom Feliciano Belt, in southeast South America, based on geochronological
20 and oxygen zircon isotope studies in metavolcanic rocks interleaved with
21 metasedimentary sequences. We present new U-Pb and O isotope data on zircons of
22 para- and ortho-derived rocks from two Tonian metavolcano-sedimentary
23 complexes: Várzea do Capivarita and Porongos. The results are compared with
24 geochronological and oxygen zircon isotopic data reported for these complexes in the
25 literature, in addition to data for the Cerro Olivo Complex (Uruguay), and provide new
26 insights on the tectonic evolution of a belt that runs along the actual southeastern South
27 America and southwestern Africa coasts. Our data provide evidence for a connection
28 between the early Neoproterozoic pre-tectonic processes (at 800-770 Ma) in the
29 hinterland and foreland of the Dom Feliciano Belt in southernmost Brazil.

30 31 **2. GEOLOGICAL SETTING**

32 33 ***2.1 Dom Feliciano–Kaoko–Gariiep Orogenic System***

34

35 The study area is located in the Dom Feliciano Belt (DFB, Fig. 1). The DFB is the
36 South American counterpart of a NS-trending Neoproterozoic orogenic system that
37 also involves the African Kaoko and Gariiep belts. The overall architecture of this
38 orogenic system has developed during the tectonic events that happened between ca.
39 800 Ma and 550 Ma (Frimmel & Frank, 1998; Oriolo et al., 2017). The ca. 800 Ma
40 Neoproterozoic units, which consist of igneous complexes of this age, are interpreted
41 by some authors as related to a continental arc (Koester et al., 2016; Martil et al., 2017;
42 De Toni et al., 2020b) or as generated in a back-arc/rift setting (Konopásek et al., 2018;
43 Will et al., 2019). The system evolved into a contraction tectonic regime generating a
44 ca. 650-620 Ma transpressive regime in the Dom Feliciano Belt (e.g. Gross et al., 2006,
45 2009; Oyhantçabal et al., 2009; Lenz et al., 2011; Martil, 2016; Peel et al., 2018; Will
46 et al., 2019; De Toni et al., 2020a; Percival et al., 2021, 2022). The contraction
47 continued until at least 580–550 Ma, as recorded by ongoing crustal thickening and
48 associated metamorphism in the orogenic system of African and South American sides
49 (Frimmel and Frank, 1998; Goscombe and Gray, 2008; Höfig et al., 2018; Percival et
50 al., 2022). Such convergent period is related to the final amalgamation of the
51 Gondwana supercontinent (e.g. Rapela et al., 2011; Ramos et al., 2017; Oriolo et al.,
52 2017; Schmitt et al., 2018).

53 In southernmost Brazil, the DFB is usually divided into Western, Central and
54 Eastern domains (Fragoso-Cesar et al., 1986; Fernandes et al., 1992; Basei et al.,
55 2000 - Fig. 1). The Western Domain comprises the Pre-Neoproterozoic basement (2.5
56 to 2.0 Ga - Hartmann et al., 2000) intruded by arc-related rocks of Tonian–Cryogenian
57 ages (the São Gabriel Arc; 750–680 Ma - Nardi and Bitencourt, 2007; Philipp et al.,
58 2016b).

59 The Central Domain is represented by low- to medium-grade volcano-
60 sedimentary rocks (Porongos Complex; Jost and Bitencourt, 1980 - Fig. 1) of Tonian
61 to Ediacaran age (e.g. Saalman et al., 2011; Pertille et al., 2017; Höfig et al., 2018)
62 with locally exposed Paleoproterozoic basement (Encantadas Complex; 2.26–2.0 Ga
63 – (Hartmann et al., 2003; Philipp et al., 2008). Both the Central and Western Domains
64 are partially covered by late-orogenic, Ediacaran to Ordovician volcano-sedimentary
65 rocks (Paim et al., 2014). Considering the portion of the orogenic belt closer to the
66 undeformed continental interiors as forelands, and the internal part of the orogen closer
67 to the high-grade core as hinterland (*sensu* Van Der Pluijm and Marshak, 2003), the
68 Western and Central domains of DFB are interpreted as belonging to the foreland.

69 The Eastern Domain represents the hinterland and features mainly granitic rocks.
70 These batholiths are interpreted as a post-collisional granitic belt (Bitencourt and Nardi
71 1993; Bitencourt and Nardi 2000; Philipp and Machado, 2002), whose emplacement
72 was controlled by a lithospheric-scale discontinuity called Southern Brazilian Shear
73 Belt (SBSB) active between ca. 650 and 580 Ma (Bitencourt & Nardi, 2000; Nardi &
74 Bitencourt, 2007). In Brazil, the Neoproterozoic granitic rocks contain roof pedants of
75 at least three distinct ages: Paleoproterozoic (2.2 and 2.0 Ga – Leite et al., 2000;
76 Gregory et al., 2015), Mesoproterozoic (ca. 1.5 Ga – Chemale et al., 2011) and Tonian
77 (ca. 800-770 Ma - Martil et al., 2011, 2017). The latter are the high-grade metamorphic
78 rocks known as *Várzea do Capivarita Complex (VCC)* (Fig. 1), which are, according to
79 many authors (e.g. Oyhantçabal et al., 2009; Martil et al., 2017; Konopásek et al.,
80 2018), related with the high-grade rocks of the Cerro Olivo Complex (Masquelin et al.,
81 2011) in the Uruguayan part of the DFB hinterland (Fig. 1).

82

83 **2.2. Tonian metavolcano-sedimentary sequences from DFB**

84

85 ***2.2.1. Várzea do Capivarita Complex - Neoproterozoic high-grade*** 86 ***metamorphic rocks in southernmost Brazil***

87

88 The *Várzea do Capivarita Complex (VCC - Martil et al., 2011, 2017)* comprises
89 part of the basement intruded by Late Neoproterozoic granites in the southernmost
90 Brazil (Fig.1). It is interpreted as a *W-verging* nappe body thrust onto the Central
91 Domain (Martil et al., 2017; Battisti et al., 2018; De Toni et al., 2021). These well-
92 preserved roof pendants (Martil et al., 2017 - Fig. 2) comprise tectonically interleaved
93 granulite facies orthogneisses and paragneisses (Martil et al., 2011, 2017). According
94 to these authors, the orthogneisses are mostly tonalitic and related to a Tonian mature
95 magmatic arc (790–780 Ma - U–Pb zircon). Paragneisses comprise metapelites and
96 calc-silicate rocks (Martil et al., 2011). The VCC was intruded by syntectonic to post-
97 tectonic plutons from ca. 629 Ma to 578 Ma (e.g. Philipp and Machado, 2002; De Toni
98 et al., 2016; Lyra et al., 2018; Padilha et al., 2019).

 118 al., 2006; Chemale et al., 2011; Philipp et al., 2016a; Martil et al., 2017); 12-(Chemale et al., 2011); 13-
 119 (Leite et al., 2000; Hartmann et al., 2003; Saalman et al., 2011; Gregory et al., 2015).

120

121 Two main deformation phases are described in the VCC and are related to one
 122 single tectono-metamorphic event under granulite facies conditions (Gross et al., 2006;
 123 Martil, 2016). VCC gneisses were tectonically interleaved along a sub horizontal
 124 banding, with top-to-the-west shear sense (Martil et al., 2011; Martil, 2016). Dextral

125 strike-slip to slightly oblique vertical NNE-SSW shear zones superpose the thrusting in
126 a progressive deformation (Martil, 2016). The granulite-facies conditions achieved ca.
127 750–800°C and 3–5 kbar in the VCC metapelites (Gross et al., 2006; Costa et al.,
128 2020; De Toni et al., 2021) at 650–640 Ma (Martil, 2016).

129 Provenance zircon U-Pb SHRIMP studies of the VCC metasedimentary rocks
130 performed by Gruber et al. (2016a) indicated ages of 2.3 – 2.0 Ga, 1.5 Ga, 1.3 Ga, 930
131 and 730 Ma for the main source areas, and the maximum deposition age was
132 estimated at 728 ± 11 Ma. According to the same authors, associated marbles were
133 deposited in an interval of ca. 717–750 Ma ($^{87}\text{Sr}/^{86}\text{Sr}$ initial ratio in whole-rock
134 analyses).

135

136 **2.2.2. Cerro Olivo Complex Complex - Neoproterozoic high-grade** 137 **metamorphic rocks in Uruguay**

138

139 Roughly going southwards along strike, in the Uruguayan part of DFB, crops out
140 the Cerro Olivo Complex (COC - Fig. 1). It is a metamorphic-plutonic complex with E–
141 W to NW–SE tectonic foliation crosscut by NE-SW strike–slip shear zones (Masquelin
142 et al., 2011). Protolith ages of the COC orthogneisses are reported to be ca. 800-760
143 Ma (Hartmann et al., 2002; Oyhantçabal et al., 2009; Lenz et al., 2011; Basei et al.,
144 2011; Masquelin et al., 2011; Will et al., 2019). Peak metamorphic conditions have
145 been determined at 830–950 °C and 7–10 kbar (Gross et al., 2009), dated at ca. 650
146 Ma (Gross et al., 2009; Oyhantçabal et al., 2009; Lenz et al., 2011; Basei et al., 2011;
147 Peel et al., 2018; Will et al., 2019) and this metamorphic event is interpreted as related
148 to the assembly of the Gondwana supercontinent.

149

150 **2.2.3. Porongos Complex – Neoproterozoic low- to medium-grade metamorphic** 151 **unit in Southernmost Brazil**

152

153 The Porongos Complex (PC; Jost and Bitencourt, 1980) is interpreted as part of
154 the Dom Feliciano Belt western foreland and comprises Neoproterozoic supracrustal
155 rocks metamorphosed at lower greenschist to middle amphibolite facies (Fig. 1 and 2).
156 The PC comprises metasedimentary and metavolcanic rocks, some ultramafic lenses
157 and, less often, deformed granitoids (Jost & Bitencourt, 1980; Marques et al., 2003;
158 Zvirtes et al., 2017). The PC metamorphic grade increases from west to east, and
159 staurolite-bearing metapelites at the PC easternmost border (Fig. 2) record the highest

160 metamorphic grade of the complex (Jost & Bitencourt, 1980; Lenz, 2006). The PT
161 conditions were estimated at 560–580°C and 5.8–6.3 kbar by De Toni et al. (2021) and
162 the metamorphism was dated at 658 ± 26 Ma (Lenz, 2006; Rb–Sr in muscovite and
163 whole-rock).

164 Provenance studies in the PC have shown two distinct sources for the
165 metamorphosed clastic sediments (Gruber et al., 2011; Pertille et al., 2015a, 2015b,
166 2017; Höfig et al., 2018). Based on this difference, Höfig et al. (2018) suggested that
167 the precursor of the Porongos Complex could have been two distinct and diachronous
168 basins. The older PC metasedimentary rocks (mostly at its eastern part – Fig. 2)
169 represent mostly clastic infill of a pre-orogenic basin with dominant Paleoproterozoic
170 (2.0–2.3 Ga), subordinate Mesoproterozoic (1.2–1.5 Ga) and rare ca. 750–800 Ma
171 detrital sources (provenance interval: 750 Ma to 3.0 Ga - Gruber et al., 2016b; Pertille
172 et al., 2017; Höfig et al., 2018). The younger PC basin presents metasedimentary rocks
173 related to the syn-orogenic (from ca 650 Ma) evolution, as discussed by Höfig et al.
174 (2018) and Battisti et al. (2018). In the western part of the PC (Fig. 2), the syn-orogenic
175 metasedimentary rocks are interleaved with the rocks of the older basin. Their detrital
176 zircon populations show mainly Paleoproterozoic (2.0–2.3 Ga) and Neoproterozoic (ca
177 600 and ca 800 Ma) sources (provenance interval: 570 Ma to 3.2 Ga - Pertille et al.,
178 2015b, 2017; Gruber et al., 2016b; Höfig et al., 2018). Associated intermediate to acid
179 metavolcanic rocks also yielded contrasting ages in different regions of the complex.
180 The PC eastern region contains metavolcanic rocks with protolith ages of ca 800–770
181 Ma (Saalman et al., 2011; Pertille et al., 2017), whereas magmatic ages of 600 and
182 601 Ma were obtained for metavolcano-sedimentary rocks of the PC western region
183 (LA–MC–ICP–MS, U–Pb zircon - Höfig et al., 2018). Such dataset shows that the
184 igneous activity and late sedimentation in the western PC is younger than the
185 metamorphic peak recorded in its eastern portion (658 ± 26 Ma - Lenz, 2006). The so-
186 called Eastern and Western Porongos Complex regions are distinguished based on
187 their position relative to the main W-verging thrust fault, the Santana da Boa Vista
188 Thrust Fault, as originally defined by Jost and Bitencourt (1981 – fig. 2).

189

190 **3. PETROGRAPHY**

191

192 Four representative samples were selected considering previous detailed field
193 studies (location in Fig. 2). Three samples represent the lithological variations of the
194 Várzea do Capivarita Complex. They include orthogneisses of tonalitic (TM-36F), or

195 granitic composition(TM-45G) and an aluminous paragneiss (TM-36S), all
196 metamorphosed under granulite facies conditions. The tonalitic orthogneiss and the
197 aluminous paragneiss are interleaved along a flat-lying foliation related to the main
198 deformation phase D₁ (Martil, 2016). The granitic orthogneiss sample has a subvertical
199 fabric S₂ in high-strain zones that overprint the flat foliation. A sample of metavolcanic
200 rock (TM-26A) with geochemical features and structural evolution similar to the VCC
201 samples (Martil, 2016; Martil et al., 2017; Battisti et al., 2018), was collected in the
202 eastern portion of the Porongos Complex, at the contact of Central and Eastern
203 domains (Fig. 1 and 2). Outcrop features of the investigated samples are shown in
204 figure 3.

205 Sample TM-36F is a poorly-banded, fine- to medium-grained hornblende-biotite
206 tonalitic orthogneiss with granolepidoblastic seriate–interlobate texture (Fig. 4a, b).
207 Rounded plagioclase megacrysts and rare K-feldspar are ca. 1 mm-large but can reach
208 up to 3 mm. They are set in a fine-grained (0.3 mm) matrix containing plagioclase, K-
209 feldspar, quartz and biotite (Fig. 4b). Biotite is subhedral and does not form well-
210 developed bands. Remnant orthopyroxene is locally preserved in pseudomorphic
211 clusters in which hornblende crystals up to 0.5 mm long with nematoblastic to
212 decussate texture and biotite crystals have grown at the expense of the former
213 orthopyroxene. Secondary chlorite, opaque minerals and zircon are also present.

214 Sample TM-36S is an irregularly banded, dark-grey coloured, sillimanite-bearing
215 garnet-cordierite-biotite paragneiss from the same outcrop as the previous sample
216 (Fig. 3). Mafic-rich bands are up to several cm thick and alternate with felsic
217 bands/lenses of millimetre thicknesses (Fig. 4c). Biotite is the main mafic mineral,
218 displaying continuous bands with 0.3 and 0.5 mm-size subhedral crystals. Felsic bands
219 are composed of 0.5 to 1 mm large quartz, less plagioclase and rare K-feldspar, all of
220 which exhibit granoblastic interlobate to granoblastic polygonal texture (Fig. 4d).
221 Garnet and cordierite are present in both mafic- and felsic-rich layers. Garnet is
222 subhedral (0.5 to 1 mm), poikiloblastic and includes numerous quartz crystals.
223 Cordierite is commonly transformed into pinnite. Rare dark-green chromium-rich spinel
224 is preserved as inclusions in cordierite. The rock contains rare tiny sillimanite crystals
225 (0.1 mm), apatite and zircon. The interpretation of sample TM-36S as a paragneiss is
226 based on the following criteria: i) At the same outcrop, TM-36S is interleaved with
227 calcsilicate layers, while in TM-36F tonalitic orthogneiss bands, calcsilicate layers are
228 absent; and ii) The amount of quartz is larger than the feldspar content in TM-36S,
229 which is not expected for a granitic origin.

230

231

232

233 Figure 3. A) Fine-grained TM-36F orthogneiss. B) Outcrop of the sampled paragneiss TM-36S
 234 with local veins resulting from partial melting. C) TM-45G granitic orthogneiss. D) Outcrop view
 235 of the metarhyolite TM-26 A.

236

237 Sample TM-45G is a granolepidoblastic, well-foliated garnet-biotite granitic
 238 orthogneiss (Fig. 4e, f) of medium-grained equigranular texture. Plagioclase, K-
 239 feldspar and quartz exhibit high-temperature recrystallisation features. Biotite crystals
 240 are 1 to 2 mm long and occur in mm-thick, mica-rich layers. Garnet is an accessory
 241 mineral with 0.2 to 0.5 mm. Zircon crystals are 0.05–0.1 mm long and exhibit zonation
 242 visible in the transmitted light.

243

244

245

246 Figure 4. The four studied samples (location in fig. 2): three are from Várzea do Capivarita
 247 Complex: A) and B) TM-36F - tonalitic orthogneiss; C) and D) TM-36S - paragneiss; and E)
 248 and F) TM-45G - granitic orthogneisses. One sample is from the Porongos Complex eastern
 249 region: G) and H) TM-26A - blastoporphyratic metarhyolite. Thin-section locations and pictures
 250 of detailed areas are indicated. Note at the right column that photomicrographs were taken in
 251 both plane-polarized (PPL) and cross-polarised light (XPL) to highlight textural aspects of the
 252 rock. Mineral abbreviations: Qz – quartz, Plg – Plagioclase, KFd – K-feldspar, Bt – biotite, GBt –
 253 green biotite, Hbl – hornblende, Grt – garnet, Cdr – cordierite.

254 TM-26A is a PC blastoporphyritic metarhyolite with ca. 3 mm-long aggregates of
255 blue quartz (Fig. 4g, h) set in a very fine-grained (0.01 mm) granolepidoblastic matrix
256 composed of quartz, feldspar and greenish biotite (Fig. 4h). Millimetre-sized quartz
257 aggregates are often stretched, and quartz crystals are either partially or completely
258 recrystallized to granoblastic texture with interlobate contacts. Larger brown biotite
259 crystals (0.2 mm) display poorly-developed, mm-thick layers. Accessory minerals are
260 opaque minerals (mainly ilmenite), apatite and zircon.

261

262 4. ANALYTICAL TECHNIQUES

263

264 The samples were crushed and the zircons were separated using standard
265 magnetic and heavy liquid density separation techniques. The clean zircon separates
266 were mounted in epoxy at the Research School of Earth Sciences (RSES), in
267 Australian National University, together with the RSES reference zircon AS3 and SL13.
268 Zircon grains were handpicked under a binocular microscope or, in the case of the
269 detrital zircons, scattered onto double-sided tape prior to mounting in epoxy to ensure
270 a random selection of grains.

271 Photomicrographs of all zircons were taken in transmitted and reflected light and
272 these, together with SEM cathodoluminescence (CL) images, were used to decipher
273 the internal structures of the sectioned grains and to select specific areas within the
274 zircons for spot analysis. U–Pb analysis was carried out using SHRIMP I, SHRIMP II
275 and SHRIMP RG at the RSES. The data were reduced in a manner similar to that
276 described by (Williams, 1998, and references therein), using the SQUID-1 Excel Macro
277 of Ludwig (2003). For the zircon calibration the Pb/U ratios were normalized relative to
278 a value of 0.1859 for the $^{206}\text{Pb}/^{238}\text{U}$ ratio of AS3 reference zircons, equivalent to an
279 age of 1099 Ma (Paces & Miller, 1993). U and Th concentrations were determined
280 relative to the SL13 standard. Uncertainties given for single analyses (ratios and ages)
281 are at the 1σ level, but uncertainties in any calculated weighted mean, concordia age
282 (Paces & Miller, 1993) or intercept age are reported as 95% confidence limits (unless
283 indicated otherwise) and include the uncertainties in the standard calibrations where
284 appropriate. Concordia plots, regressions and age calculations were carried out using
285 Isoplot/Ex and SQUID-1 (Ludwig, 2003). Zircon oxygen isotopic data were analyzed
286 by SHRIMP SI and, when possible, spots were made directly below to the polished
287 locations of ages measurements. All δO_{18} data were normalized to a TEMORA II value

288 of 8.2‰. Complete data of analyzed zircons from each sample are presented as
289 supplementary data.

290

291 **5. U-Pb RESULTS IN ZIRCON**

292

293 **5.1. Orthogneisses (TM-36F and TM-45G)**

294

295 Samples TM-36F and TM-45G were analysed to determine the crystallisation age
296 of the VCC tonalitic and granitic composition protolith, respectively. In TM-36F, the
297 zircon population is rather homogeneous, and the grains are euhedral to subhedral
298 with shapes ranging from square and almost equidimensional to more elongate
299 prismatic forms (Fig. 5a). CL imaging reveals that internal structures are dominated by
300 sectors with oscillatory zoning of variable intensity. Crystal sizes are ca. 100–250 μm .
301 Some crystals show a core with no zoning, which grades into the oscillatory-zoned
302 rims, the latter showing the most concordant analyses (Fig. 6a). Nineteen spot
303 analyses in the oscillatory zoned domains yielded an upper intercept age of 786 ± 18
304 Ma (2σ) (Fig. 6b). Discarding the three youngest domains, a concordia age of 786 ± 5
305 Ma was calculated (95% confidence), which is considered the best estimate for the
306 crystallization age of the igneous protolith (Fig. 6c). Th/U ratios determined for the
307 concordant spots range between 0.28 and 0.68. One crystal (#14.1) without oscillatory
308 zoning and Th/U ratio of 0.84 gave a Mesoproterozoic concordant age of 1119 ± 40
309 Ma (Fig. 4c, 5a), interpreted here as an inherited grain.

310 Zircon population from sample TM-45G is rather homogeneous and shows
311 euhedral to subhedral, mainly elongate prismatic crystals smaller than 200 μm . Their
312 CL images show typical igneous oscillatory zoning (Fig. 5b). Some crystals present an
313 inner part with no zoning and a light grey area at the rims. Most zircon crystals have a
314 very thin, CL-bright rim, which probably indicates a metamorphic overgrowth; however,
315 the rims are too thin for analysis. Twenty-two SHRIMP analyses were performed in ten
316 different zircon grains, and eleven analyses, with Th/U ratios between 0.16 and 0.54
317 yielded a mean $^{207}\text{Pb}/^{206}\text{Pb}$ age of 790 ± 7 Ma (MSWD = 0.69; probability of
318 concordance = 0.73), which is interpreted as the age of the orthogneiss protolith (Fig
319 7). Two spots yielded concordant dates at ca. 1.8 and 2.0 Ga, and these are interpreted
320 as inherited grains. Other older grains were dated, but with discordant ages (Fig. 7a).

 339 orthogneiss. B) Concordant Neoproterozoic zircons used to calculate the mean $^{206}\text{Pb}/^{207}\text{Pb}$,
 340 interpreted as the crystallisation age of the ortho-derived protolith.

341

342 **5.2. Paragneiss (TM-36S)**

343

344 To constrain the maximum age of sedimentation for the VCC, 65 zircon grains
 345 were analysed from the paragneiss sample TM-36S. The CL images show typical
 346 igneous oscillatory zoning, and the crystal sizes are between 50 and 200 μm . Most
 347 crystals are prismatic, euhedral to sub-euhedral (Fig. 5c) with no sign of abrasion, and
 348 their sharp pyramidal tips are preserved. Thin CL-bright overgrowths are rare and too
 349 thin to be analysed.

350 The data is shown in two separate concordia diagrams and one relative
 351 probability plot (Fig. 8). Considering only the concordant (>95%) analyses, detrital
 352 zircon grains from sample TM-36S provided two populations: a minor one at ca. 1.1

353 Ga, and a more significant at ca. 790 Ma (Fig.8). Some discordant grains suggest older
354 sources (Fig. 8a).

355 The 790-750 Ma age interval indicates a major source for the deposition of these
356 para-derived protoliths (Fig. 8b). The analysed grains show Th/U ratios between 0.18
357 and 0.70, although spot #23.1 has a Th/U ratio of 0.08. The data spread is centred at
358 ca. 790 Ma, which corresponds also to the crystallization age of the tonalitic
359 orthogneiss TM-36F, as shown by curves of relative probability (Fig. 8c). This would
360 suggest that they are coeval or that the sedimentary protolith of sample TM-36S is
361 mostly a product of erosion of the 790 Ma tonalite/dacite. The predominantly euhedral
362 detrital zircons with well-preserved prismatic tips indicate a short sedimentary transport
363 (near to source). The two youngest detrital zircons constrain the maximum age of
364 sedimentation at 716 Ma (spots 31.1 and 41.1 - at the bottom of Fig 5c).

365 One crystal reveals a much younger age of 632 ± 9 Ma (spot 6.1 – Fig. 5c, 8b). It
366 is interpreted as related to the metamorphic granulite facies event because it is
367 morphologically distinct from the others with a homogenous black domain and has
368 Th/U ratio of 0.01.

369

 375
 376
 377
 378

Figure 8. A) Concordia U-Pb diagram with all zircons analysed from sample TM-36S, a paragneiss. B) Zoom in Fig. 8A, showing the Neoproterozoic population of detrital zircons. C) Histogram with the detrital zircon population of sample TM-36S (in black). Note the curve of relative probability for TM-36S compared to the relative probability curve of the igneous zircons from the orthogneiss sample TM-36F (in red). The calculated crystallisation age of the orthogneiss is shown in the dashed red line.

379 **5.3. Metarhyolite (TM-26A)**

380

381 Sample TM-26A shows zircons 100 to 300 μm long with elongate prismatic habits
382 and well-preserved to sub-rounded bipyramidal tips (Fig. 9a). Some zircon grains
383 display darker cores, sometimes with well-defined oscillatory zoning. The U-Pb ages
384 reveal that the rounded cores are inherited zircon grains, and the oscillatory-zoned
385 overgrowths or rims represent magmatic zircon.

386 Twenty-three SHRIMP analyses were performed in fifteen different zircon grains,
387 and the resulting data were plotted in conventional Wetherill U–Pb concordia diagram
388 (Fig. 9b, c). In this dataset, 17 spots represent the most concordant analyses, whereas
389 the data with discordance higher than 5% were excluded. Fifteen analyses of grains,
390 with Th/U ratios between 0.26 and 0.67, define a concordia age of 787 ± 5 Ma (2σ),
391 which is interpreted as the best estimate for crystallization of the volcanic protolith (Fig.
392 9c).

393 Although most of the analyses on xenocrystic cores yielded highly discordant
394 data, two spots (#11.2 and #14.2 - Th/U ratios of 0.65 and 0.44 – Fig. 9a) yielded nearly
395 concordant data suggesting ages of ca. 2.0 Ga. Both also have oscillatory overgrowths
396 of ca. 760 Ma, suggesting that the protolith age of crystallization is Tonian, and the
397 Paleoproterozoic core might indicate a source partially melted during the Tonian
398 magmatic event.

399 The other two spots with discordance <10% yielded $^{206}\text{Pb}/^{238}\text{U}$ dates represent
400 inheritance (Fig. 9b). Spot #2.1 gave a date around 2.0 Ga; however, the Th/U ratio is
401 relatively low (0.03) compared to the inherited concordant cores of similar age. Spot
402 #8.1 indicates a core of approximately 2.5 Ga and a Th/U ratio of 0.62.

C) Neoproterozoic zircons enlarged plot, where the concordia age is interpreted as the crystallisation age of this rock.

6. OXYGEN ISOTOPES RESULTS

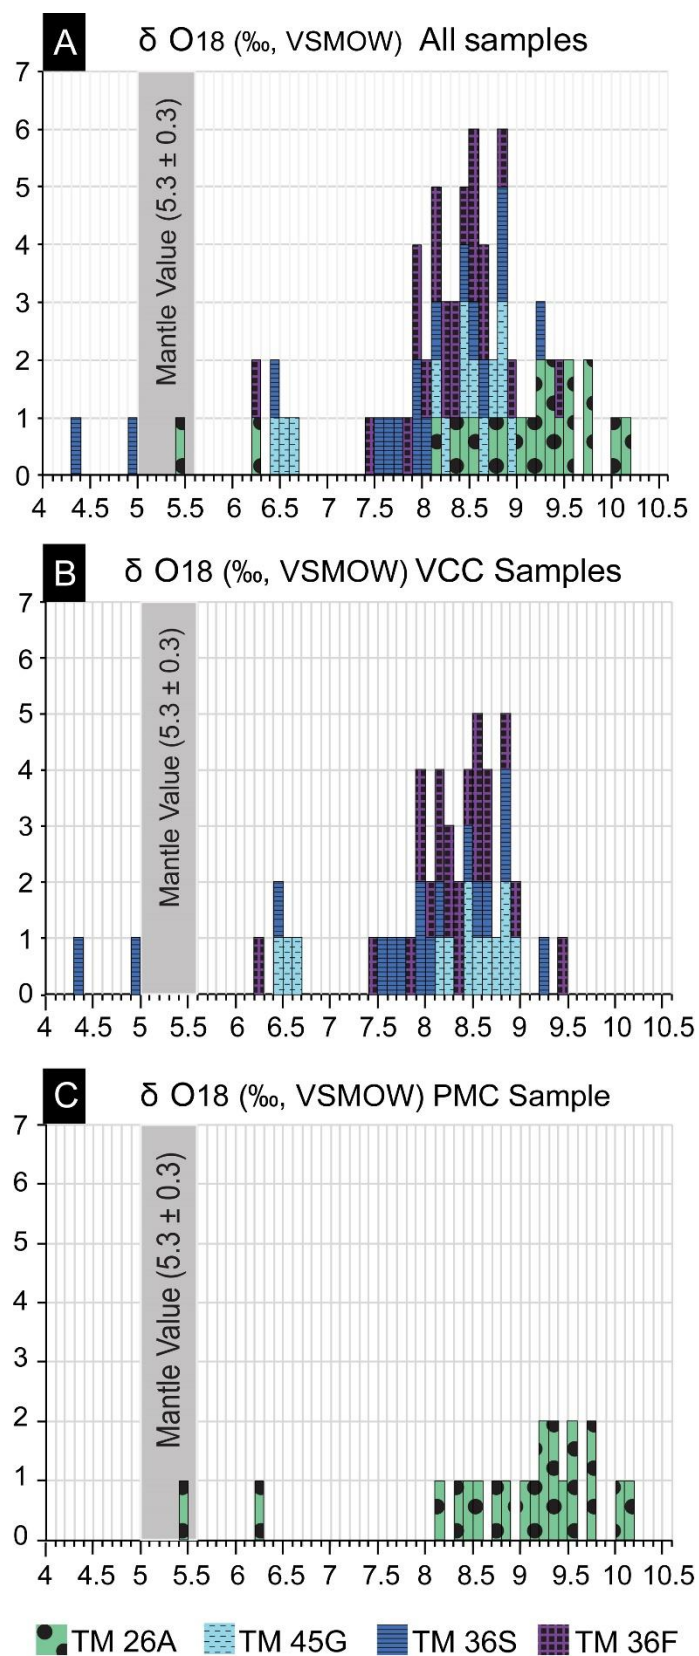

412

413

414 Oxygen isotope studies in zircon crystals are important allies to elucidate
415 processes during magma evolution (Eiler, 2001; Valley et al., 2005; Scherer et al.,
416 2007). A single zircon grain may even register more than one process, which is
417 commonly marked by its zones or intergrowths (Scherer et al., 2007). Therefore,
418 whenever possible, the U–Pb ratios and the δO_{18} values were determined in the same
419 spot to correlate the δO_{18} values with the U/Pb age of the analysed grain. The four
420 studied samples show similar δO_{18} values, most commonly ranging from 7.9‰ to 9.7‰
421 (Fig. 10a). δO_{18} values lower than 7 were registered in all samples, but values lower
422 than "mantle values" (δO_{18} mantle = 5.3 ± 0.3 ‰ – Valley et al., 1998) were only
423 measured in sample TM-36S (VCC para-derived gneiss). Only one analytical spot in
424 the PC sample (TM-26A) yielded a δO_{18} value typical for the mantle zircon crystal. The
425 highest δO_{18} value found in the VCC samples is 9.4‰, registered in the ortho-derived
426 gneiss TM-36F (Fig. 10b), whilst the highest value in the PC sample TM-26A is 10.2‰
427 (Fig. 10c).

428

429 Most of the spots were performed on Neoproterozoic igneous zircons, either on
430 their cores or rims (Fig. 11). Crystal cores (Fig. 11a) and crystal rims (Fig. 11b)
431 generally show similar δO_{18} values, although they present some differences. For
432 example, in the PC sample TM-26A, δO_{18} values measured in some zircon rims are
433 slightly higher than values from zircon cores of the same sample. Conversely, in the
434 para-derived VCC gneiss TM-36S, the calculated mean δO_{18} values are much smaller
435 in crystal rims (6.45 ± 1.48 ‰) than in crystal cores (8.03 ± 33 ‰). Nevertheless, the large
436 statistical error and standard deviation indicate that these data require caution since
437 only two spots were analysed in zircon rims of sample TM-36S (Fig. 11b). Mean δO_{18}
438 values with their error, standard deviation and number of analysed spots (n) for each
439 sample are shown in figure 11, where 11a only presents the data from igneous zircons
440 cores; 11b presents the data from igneous zircons rims and in 11c is showed all
441 statistical data together (zircons core + zircons rims). Examples of analysed zircon in
442 each sample are also shown as cathodoluminescence images, where each spot's U-
443 Pb age and δO_{18} value are indicated (Fig. 11). All analysed spots are available as
supplementary data.

444

445

446 Figure 10. Zircon oxygen isotopic values measured in the four studied samples. A) $\delta O18$ zircon447 values from all samples; B) $\delta O18$ zircon values from Várzea do Capivarita Complex samples;448 C) $\delta O18$ zircon values from Porongos Complex sample.

449

450

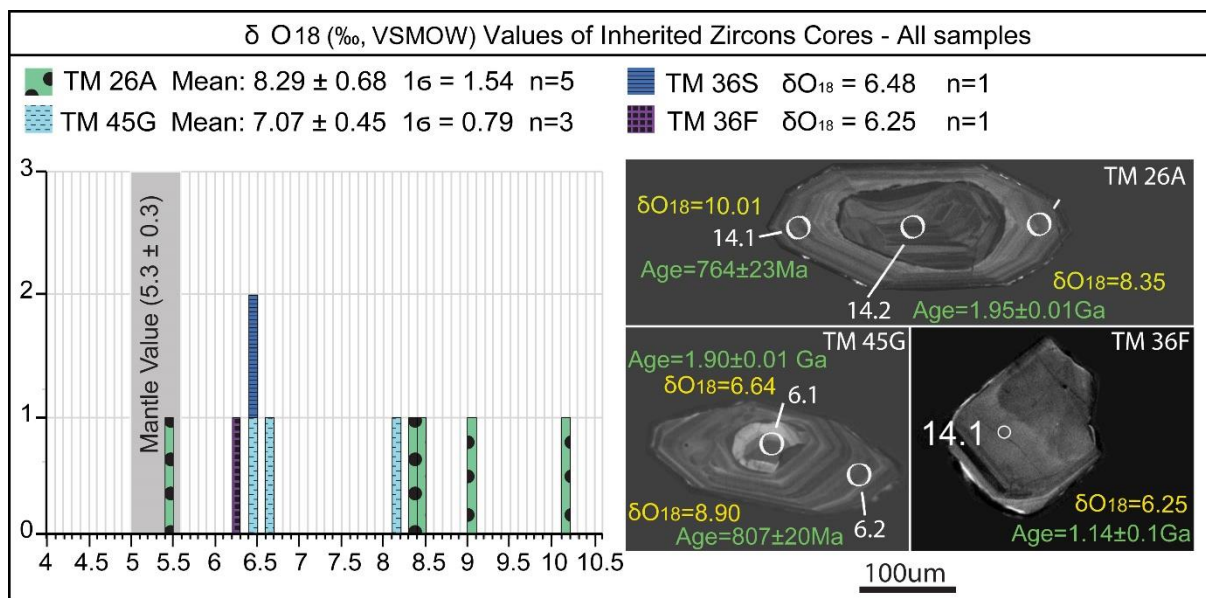

451 Figure 11 - δO_{18} values from Neoproterozoic zircons. A) Data from spots analysed in zircon
 452 cores, B) Data from spots analysed in zircon rims. C) General δO_{18} zircon values, considering
 453 all measured data (core spots + rim spots).

454

455 As described above, inherited zircons cores were registered in all studied
 456 samples. In order to compare them with Neoproterozoic igneous zircons, δO_{18} values
 457 were also measured in some of these inherited zircon cores. The results are indicated
 458 in figure 12, with their statistical data and some examples of analysed spots. As
 459 expected, many of the smallest δO_{18} values found in the studied samples are related
 460 to inherited zircons (Fig. 12). However, two points do not follow the expectations: 1)

461 the smallest δO_{18} value in sample TM-36S is related to Neoproterozoic igneous zircon
 462 and not to inherited population; 2) despite the smallest δO_{18} value of the sample TM-
 463 26A be from an inherited zircon, one spot performed in inherited zircons gave δO_{18}
 464 value (10.2‰) higher than those found to the igneous zircons ($\delta O_{18} < 10.1‰$).

465

466

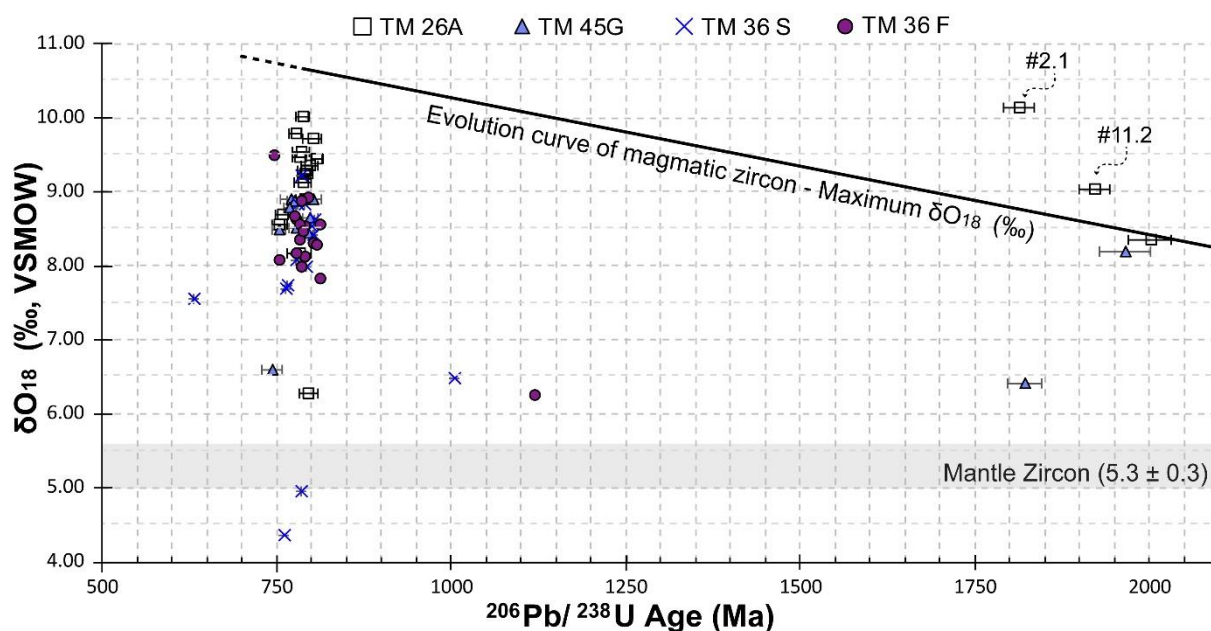

467

468 Figure 12 - δO_{18} values measured in inherited zircons cores.

469

470 The correlation of δO_{18} values with the U-Pb ages of analyzed zircon crystals,
 471 considering only the U-Pb ages with less than 5% of discordance, show no statistical
 472 correlation between those values (Fig. 13). Inherited zircons (older than 1000 Ma, in
 473 figure 13) have δO_{18} values from 6.3‰ to 10.2‰. The studied Neoproterozoic igneous
 474 zircons of 800-750 Ma have commonly δO_{18} values higher than 7.5‰ to slightly higher
 475 than 10‰, although also values around 6.5‰ and smaller than 5‰ are reported. Note
 476 in figure 13, the magmatic zircon evolution curve through the geological time (Valley
 477 et al., 2005) in which the highest expected magmatic δO_{18} values to a given age are
 478 delimited by the curve, according to Valley et al. (2005). In other words, magmatic
 479 zircons should plot under the curve. However, as shown in figure 13, two inherited
 480 zircons from PC sample TM-26A (#2.1 and #11.2) have plotted above such a curve
 481 and will be discussed later.

482

483

484 Figure 13 – δO_{18} zircon value plotted against the magmatic age of the grains (spots #2.1 and
 485 #11.2 are indicated – see text for further information). The magmatic zircon evolution curve
 486 through geological time (Valley et al., 2005) suggest the highest expected magmatic δO_{18}
 487 values to a given age. Horizontal bars indicate $^{206}\text{Pb}/^{238}\text{U}$ ages errors (\pm).

488

489 7. DISCUSSION

490

491 7.1. Timing of pre-collisional igneous events in the hinterland and foreland 492 of the Dom Feliciano Belt

493

494 The new geochronological data obtained for the Várzea do Capivarita Complex
 495 orthogneisses demonstrate the Tonian age of their protolith, with Meso- to
 496 Paleoproterozoic inheritance ages, and reveals that such rocks are related to a
 497 magmatic event at ca. 790 Ma, in the DFB hinterland. The tonalitic orthogneiss (TM-
 498 36F) yielded a concordant U-Pb SHRIMP age of 786 ± 5 Ma (2σ) with one ca. 1.1 Ga
 499 inherited zircon. Likewise, the granitic orthogneiss (TM-45G) yielded the same (within
 500 error) mean $\text{Pb}^{207}/\text{Pb}^{206}$ SHRIMP age of 790 ± 7 Ma with ca. 1.8 and 2.0 Ga inherited
 501 zircon xenocrysts. This magmatic event has the same age interval reported for the
 502 protoliths of granulitic orthogneisses in the Cerro Olivo Complex (COC) within the
 503 Uruguayan part of the DFB, further south along strike belt (Fig.1). The U–Pb SHRIMP
 504 ages for COC are: (Will et al., 2019), 802–767 Ma (Lenz et al., 2011), 782 ± 7 Ma
 505 (Masquelin et al., 2011), 761 ± 7 (Basei et al., 2011), 776 ± 12 Ma (Oyhantçabal et al.,
 506 2009) and 762 ± 8 (Hartmann et al., 2002). In the Brazilian part of the DFB, high-grade

507 igneous rocks with ca. 800-770 Ma protolith ages were discussed by Koester et al.
508 (2016), Martil et al. (2017) and De Toni et al. (2020b).

509 The Porongos Complex metarhyolite yielded a concordant U–Pb SHRIMP
510 crystallization age of 787 ± 2 Ma (2σ) with inheritance at ca. 2.0 Ga. Such age and the
511 Th/U ratios obtained in these igneous zircon grains are similar to those of the VCC
512 (Table 1). Our data represent the first dating of the metavolcanics lying at the PC
513 easternmost border (Fig. 2). The geochemical similarities of all samples studied in this
514 paper were pointed out by Martil et al. (2017) and Battisti et al. (2018). The obtained
515 age for the PC metarhyolite falls in the time interval of 800-770 Ma for pre-collisional
516 magmatic events in the PC established by previous studies (Soliani Jr, 1986;
517 Saalman et al., 2011; Pertille et al., 2017). Thus, our data is also coherent and confirm
518 that the ca. 790 Ma magmatism was also important in the DFB foreland. In our view,
519 this magmatism in the PC is mainly found eastwards of the Santana da Boa Vista thrust
520 fault (see further discussion). Furthermore, our geochronological data in meta-igneous
521 rocks demonstrate that a magmatic activity had occurred in both hinterland and
522 foreland of the DFB at ca. 790 Ma.

523

524 INSERT TABLE 1

525

526 ***7.2. Syn-volcanic sedimentation in the Várzea do Capivarita Complex***

527

528 Provenance studies in the paragneiss sample (TM-36S) demonstrated the main
529 detrital population between 790 and 750 Ma. Such detrital population is coeval with the
530 magmatic event that generated the protoliths of the orthogneisses TM-36F and TM-
531 45G from the same complex (Fig. 8C). The time interval of 790-750 Ma is also coeval
532 with the igneous protolith ages reported in the literature for the Cerro Olivo Complex in
533 Uruguay, as shown in item 7.1 (Hartmann et al., 2002; Oyhantçabal et al., 2009; Lenz
534 et al., 2011; Basei et al., 2011; Masquelin et al., 2011; Will et al., 2019). The
535 coincidence of ages in the VCC ortho and paragneisses can be interpreted in two
536 alternative ways. The protolith of the paragneiss sample originated as volcanoclastic
537 debris, as in a mature arc setting, for instance, or was deposited in a tectonically very
538 active environment, with rapid exhumation, erosion and deposition in a rift setting, for
539 instance. Both alternatives suggest short transport of the detritus that would explain
540 the preservation of the pyramidal tips of the detrital zircons (Fig. 5). The first hypothesis

541 is suggested based on the geochemical signature of the VCC orthogneisses, which is
542 compatible with that found in a mature arc setting (Martil et al., 2017).

543 The entirely similar morphology and age of the igneous and detrital zircon crystals
544 from the studied VCC samples strongly suggest that some parts of this unit might
545 represent metamorphosed syn- sedimentary volcanic or volcano-sedimentary
546 deposits. This data also implies that the interleaving of orthogneiss and paragneiss in
547 the VCC, in part, represents its original S_0 , which might have also been interleaved
548 tectonically later, during the transpressive deformation. The high metamorphic grade
549 (granulite facies) and intense deformation that affected these rocks obliterated any
550 additional depositional features of the protoliths that would permit a better
551 interpretation of their mutual relationships. One single spot (#6.1) in a zircon grain from
552 the paragneiss sample TM-36S yielded an age of 632 ± 9 Ma, which is interpreted as
553 related to such metamorphic granulite facies event, based on its distinct morphology
554 and low Th/U ratio (0.01). This interpretation is in agreement with the well-known time
555 interval for the main collision in the DFB at ca. 650–620 Ma (Gross et al., 2006, 2009;
556 Oyhantçabal et al., 2009; Chemale et al., 2011; Lenz et al., 2011; Basei et al., 2011;
557 Philipp et al., 2016a; Peel et al., 2018; Will et al., 2019; Percival et al., 2022).

558 According to Gruber et al. (2016a), the maximum depositional age for the VCC
559 clastic sedimentary rocks is 728 ± 11 Ma (U–Pb SHRIMP), and an interval of ca. 717–
560 750 Ma ($^{87}\text{Sr}/^{86}\text{Sr}$ whole rock) is proposed for the marble sequence deposition.
561 Considering the error, our data (716 ± 10 Ma) corroborate the maximum VCC
562 depositional age interpretation.

563

564 ***7.3. Interpretation and correlation of the zircon oxygen isotopic data***

565

566 The reliability of geochronological data from high-grade rocks, such as in the VCC
567 and COC, is discussed in the literature, as in the Harts Range Group, Australia, for
568 example (Maidment et al., 2013). Such preservation is common in zircon due to the
569 extremely low diffusion rates of Pb, Th and U in the crystal lattice, even at high
570 temperature and pressure (Lee et al., 1997; Cherniak & Watson, 2001, 2003; Scherer
571 et al., 2007). The diffusion rate of oxygen in zircon under high-temperature conditions
572 is also low (Peck et al., 2003), with effective closure temperatures at around 700°C
573 (Watson & Cherniak, 1997), and suggests that δO_{18} values are reliable even in high-
574 grade metamorphic rocks (e.g. Valley et al., 1994). However, in extreme cases,

575 radiation damage, metamictization and micro fracturing could facilitate the late
576 exchange of oxygen (Valley, 2003).

577 As established by Valley et al. (1998) and discussed by Bindeman (2008), among
578 many other authors, zircon in equilibrium with mantle-derived melts has an average
579 δO_{18} value of $5.3 \pm 0.3\text{‰}$. Higher δO_{18} values reflect the presence of ^{18}O -enriched
580 components, as, for instance, the melting or assimilation of crustal material or
581 hydrothermally altered oceanic crust (Peck et al., 2001; Valley et al., 2005; Kemp et
582 al., 2006). Such δO_{18} enrichment process results in an expected "evolutionary curve of
583 magmatic zircons" over the geological time (Fig. 13) (Valley et al., 2005). As predicted
584 by this curve, δO_{18} values higher than 7.5‰ are not recorded in igneous zircons older
585 than 2.5 Ga, but they are common in zircon crystallized in the Proterozoic times. Lastly,
586 zircon crystals could also present δO_{18} values lower than 5‰ . Such values commonly
587 represent shallow sub-volcanic magma chambers where low δO_{18} values resulted from
588 melting of hydrothermally altered wall rock (Bindeman & Valley, 2000; Valley, 2003;
589 Valley et al., 2005) or, less often, from the contribution of glacial ice melting in rifting
590 scenarios (Wickham & Taylor, 1985), since meteoric water has negative (to strongly
591 negative) δO_{18} values.

592 Our data demonstrate that δO_{18} values from VCC and PC samples are quite
593 similar, where the most common δO_{18} values range between 7.9‰ and 9.7‰ . δO_{18}
594 lower than 7.5‰ were registered in all studied samples, in which four of these spots
595 are related to the Neoproterozoic zircon population. Two of these spots are from the
596 paragneiss TM-36S (#24.1 and #20.1 - all analysed spots are available as
597 supplementary data). They could represent the source of detrital zircons from
598 neighbouring lithologies and thus, may not provide reliable information for further
599 interpretations about the VCC syn-volcanic-sedimentary scenario. Nevertheless, the
600 two other spots with δO_{18} values of 6.5‰ and 6.2‰ were registered in the
601 orthogneisses TM-45G and TM-26A, respectively (Fig. 11). Such values could be
602 easily explained by a lower- δO_{18} mantle-derived input (Valley, 2003). Moreover, some
603 hydrothermal water could also be responsible for reducing the δO_{18} values of such
604 Neoproterozoic grains (Bindeman & Valley, 2000). However, the crystals do not show
605 any cracks to permit such interaction. Irrespective of the meaning of those lower δO_{18}
606 zircons, only a few of them record such effect, which suggests that it was not a
607 significant event.

608 The highest value of δO_{18} found in the VCC samples is 9.4‰ , in a zircon core of
609 TM-36F (VCC orthogneiss). On the other hand, the highest δO_{18} values of the PC

610 sample are mostly related to the igneous zircon rims. Surprisingly, the highest value
611 for the PC sample was found in the core of an inherited zircon (1.96 Ga): $\delta O_{18} = 10.2\%$
612 (Fig. 11) (spot #2.1-supplementary data). Spot #2.1 is 9% discordant, it has a relatively
613 low Th/U ratio (0.03), and in figure 13 plots above the "evolutionary curve of magmatic
614 zircons". Such indications mean that this zircon is non-magmatic or, most probably, a
615 magmatic zircon affected by a younger hydrothermal or metamorphic event. As
616 suggested by the low Th/U ratio, the latter option is more probable. Spot #11.2 also
617 plots above the expected curve (Fig. 13). However, it is 2% discordant and has a Th/U
618 ratio equal to 0.65, which suggest an igneous origin for this grain.

619 As shown in figures 10, 11 and 12, only one inherited zircon crystal has
620 crystallized in equilibrium with mantle δO_{18} values. The vast majority of analysed
621 zircon grains have higher δO_{18} values following the expected evolution magmatic
622 zircon curve of Valley et al. (2005). The main calculated δO_{18} for Neoproterozoic
623 igneous zircons in all studied samples, summarized in table 1, also show higher δO_{18}
624 values than the mantle value. Such data suggest that most zircons crystallized in more
625 evolved magmas, either as a response to melting of host rocks and sediments (buried
626 and/or subducted) or as a response to the assimilation of crustal material by mantle-
627 derived magmas, as by assimilation-fractional crystallization (AFC) processes (Peck
628 et al., 2001; Valley, 2003; Kemp et al., 2006). If a subduction event is considered in an
629 arc setting (see section 7.5 for such discussion), recycling of hydrothermally altered
630 oceanic crust may also be responsible for raising the zircon δO_{18} values (Valley et al.,
631 2005). Accordingly, Martil et al. (2017) present $^{87}Sr/^{86}Sr_{(t)}$ values for the VCC, from
632 0.71628 to 0.72509, $\epsilon Nd_{(790)}$ values from -7.19 to -10.06, and Meso to
633 Paleoproterozoic Nd-TDM and inheritance ages, which these authors interpreted as "a
634 more evolved magmatic source with strong evidence of crustal assimilation/
635 contamination". Further discussions regarding the magmatic processes using the δO_{18}
636 data would require additional sampling of a larger SiO_2 range (magmatic series) to
637 correlate the fractionation of zircon δO_{18} in comparison to the δO_{18} of the whole rock.

638 The values determined in most zircon grains from the studied VCC and PC rocks
639 are in the range of Proterozoic igneous zircons, as discussed by Valley et al. (2005)
640 amongst other authors. The similarity of the zircon oxygen isotopic values for the
641 studied samples suggests a similar magmatic source for generating protoliths of the
642 VCC and PC orthometamorphic rocks. The available δO_{18} data from the literature,
643 acquired in other ortho-derived rocks from DFB with ca. 800-770 Ma protolith age
644 reinforces this statement, as demonstrated in Figure 14, where our present data are

645 compared with three other acid metavolcanics from the PC (Pertille et al., 2017) and
 646 three granulitic orthogneisses from the Cerro Olivo Complex, in Uruguay (Will et al.,
 647 2019).
 648

649
 650
 651 Figure 14. Comparison of δO_{18} zircon values among ca. 770-800 Ma ortho-derived
 652 metamorphic rocks from Brazil (Várzea do Capivarita Complex, Porongos Complex) and
 653 Uruguay (Cerro Olivo Complex).
 654

655 **7.4. Shared pre-collisional evolution of Dom Feliciano Belt hinterland and** 656 **foreland units**

657
 658 The coeval protolith ages obtained for the Várzea do Capivarita Complex (TM-
 659 36F, TM-45G) and the Porongos Complex (TM-26A) samples pointed out age

660 similarities of part of the protoliths in both units (table 2 and 3). Such temporal
661 connection, together with geochemical and structural results of Martil et al. (2017) and
662 Battisti et al. (2018), lead us to strengthen our interpretation that both complexes
663 represent different parts of a single basin at some point in their geological history.
664 According to our geochronological data from meta-igneous rocks, this connection was
665 very likely at 790–780 Ma.

666 Nevertheless, it should be noted that the PC western region contains younger
667 metavolcanic rocks (e. g. Höfig et al., 2018) and also younger sources of detrital
668 material than its eastern region, as showed by Pertille et al. (2015a, 2017), Gruber et
669 al. (2016b) and Höfig et al. (2018). These data reflect distinct evolutionary histories for
670 the western and eastern regions of the PC, as discussed by Battisti (2022). For these
671 reasons, the data discussed here indicate a direct correlation only between the VCC
672 and the PC eastern region but not with the PC as a whole. The geochronological
673 differences between the western and eastern PC rocks are summarized in tables 2
674 and 3 and figure 15. Aiming to compare DFB units, tables 2 and 3 also show the data
675 from granulitic rocks of the Cerro Olivo Complex in Uruguay.

676 As seen in Figure 13, the δO_{18} values in zircon also demonstrate a direct
677 correlation between ortho metamorphic samples from the VCC and PC eastern region.
678 Moreover, zircon δO_{18} also point out a correlation between the ca. 800-770 Ma
679 magmatic event in Brazil and Uruguay, as already suggested in other
680 geochronological, isotopic and structural studies (e.g. Basei et al., 2000; Martil et al.,
681 2017; Konopásek et al., 2018; De Toni et al., 2020b).

686

687

688

689

690 Figure 15. Geological map of the study area illustrating the sample sites from Tables 2 and 3.
 691 Please note the similar magmatic and provenance ages between VCC and eastern PC and
 692 the difference between the magmatic and provenance ages between the PC eastern and
 693 western regions - separated by the Santana da Boa Vista thrust fault (inset sketch). Eastern
 694 PC has mainly provenance sources older than the main metamorphic-deformational event (at
 695 ca. 650 Ma), and the western PC has provenance sources both older and younger than this
 696 time. Circles are magmatic ages, while squares represent provenance source ages.
 697 Abbreviations: Pp – Paleoproterozoic, Mp – Mesoproterozoic, Np – Neoproterozoic.
 698 References are the same as in figure 2.

699

700 While the correlations among various meta-igneous rocks of early
 701 Neoproterozoic age are straightforward, the correlation of metasedimentary rocks from
 702 the PC and VCC requires more caution. That is because the detrital provenance in the
 703 PC rocks is much better studied than in the VCC ones. However, keeping this in mind,

704 some considerations can be made. Both complexes present a similar detrital interval
705 for pre-collisional metasedimentary rocks: 750 Ma – 3.0 Ga for PC (Gruber et al.,
706 2016b; Pertille et al., 2017; Höfig et al., 2018), and 730 Ma – 2.5 Ga for VCC (Gruber
707 et al., 2016a). Regarding the main age peaks, the PC rocks show two main peaks (1.2–
708 1.5 and 2.0–2.3 Ga), while the VCC samples show only one well-marked peak at 1.9–
709 2.2 Ga (Gruber et al., 2016a). Moreover, the well pronounced ca 790 Ma age peak
710 found in the paragneiss TM-36S has not yet been registered in the VCC
711 metasedimentary rocks, although individual data showing such detrital age were
712 reported by Gruber et al. (2016a) also in other parts of the VCC.

713 On the other hand, it is important to point out that the latter two differences may
714 be explained by a shortage of data from the VCC. Thus, we interpret that the absence
715 of age peaks at ca. 1.2-1.5 Ga in the VCC will probably be solved when sufficient
716 detrital studies are available. Therefore, despite the caution considered in interpreting
717 the relationship between the para-metamorphic rocks of VCC and PC, they also
718 suggest a shared depositional origin by VCC and PC, indicated by our data in the ortho-
719 metamorphic rocks of both complexes.

720

721 ***7.5. The geological setting of ca. 800-770 Ma magmatic event***

722

723 The geological setting in which the ca. 800-770 Ma metagneous rocks of the
724 DFB was generated is debatable. Two main interpretations are found in the literature,
725 and for this reason, a continental arc (Koester et al., 2016; Martil et al., 2017; De Toni
726 et al., 2020b) or a back-arc/rift setting (Konopásek et al., 2018, 2020; Will et al., 2019)
727 are assumed as possible environments. Geochemical and isotopic features favour the
728 first hypothesis (Martil et al., 2017; De Toni et al., 2020b), and the structural data are
729 not discriminant. However, this discussion is not the focus of the present work, and
730 apart from the zircon oxygen isotope data, our data does not bring further arguments
731 to this discussion. Moreover, our zircon data demonstrate that the generation of 800-
732 770 protoliths has involved contamination/assimilation of crustal material, which is very
733 likely in both scenarios. Finally, it is important to highlight that our proposed VCC-PC
734 syn-volcano-sedimentary environment is not exclusive of either a continental arc or a
735 back-arc/rift. For that reason, our model is supported in both scenarios, as shown in
736 figure 16.

Figure 16. Models proposed in the literature for the study region: Hypothesis 1 is an idealised drawing after the discussion of Konopásek et al. (2020), in which a rift/back-arc scenario was responsible for generating 800-770 Ma VCC, PC and COC ortho-protoliths. Hypothesis 2 is a redrawing of De Toni et al. (2020b), in which the authors proposed arc magmatism as the best scenario for the emplacement of 800-770 Ma VCC, PC and COC ortho-protoliths. The syn-volcano-sedimentary environment proposed in this paper is achievable in both situations, irrespective of the chosen model.

747 Thus, our geochronological and isotopic data suggest that at least part of the
748 VCC represents former sedimentary rocks that originated through erosion of coeval
749 igneous rocks. Furthermore, the similar age and isotopic record of zircon in the VCC
750 and PC meta-igneous samples raises the hypothesis that the Várzea do Capivarita
751 Complex and part of the Porongos Complex represent different portions of a former
752 single volcano-sedimentary basin (Fig. 16). This basin was inverted at ca. 650 Ma by
753 progressive dextral/top-to-W transpressive deformation resulting in exhumation and
754 thrusting of its deeper and hotter part (VCC) over its margins (PC) (Fig. 16). However,
755 the contact between VCC and PC is now obliterated by younger magmatic activity.
756 After the basin inversion, such contact was probably represented by thrust faults, as
757 discussed in Battisti et al. (2018). The age of ca. 650–620 Ma for this inversion event
758 is supported by several authors in Brazil (in VCC: Gross et al., 2006; Chemale et al.,
759 2011; Martil, 2016; Philipp et al., 2016; in PC: Lenz, 2006, Battisti, 2022 and in Uruguay
760 Gross et al., 2009; Oyhantçabal et al., 2009; Lenz et al., 2011; Basei et al., 2011; Peel
761 et al., 2018; Will et al., 2019). The relationship between the high-grade Uruguayan
762 rocks and VCC–PC basin is more obscure. However, our isotopic comparison and
763 many other isotopic and geochronological data from the literature show that the
764 generation of all these rocks is probably the result of the same tectono-magmatic
765 evolution.

766

767 8. CONCLUSIONS

768

769 New geochronological data indicate that the Várzea do Capivarita Complex
770 (VCC) in southernmost Brazil has, at least in part, a syn-volcanic–sedimentary origin
771 at ca. 790 Ma. The geochronological dataset also constrains a maximum depositional
772 age of 716 ± 10 Ma for the VCC original basin. The geochronological and zircon oxygen
773 isotopic similarities shown for the VCC and Porongos Complex (PC) samples imply
774 igneous protoliths of the Várzea do Capivarita Complex. They also imply that part of
775 the Porongos Complex (mostly its eastern region) has represented different parts of a
776 single basin at ca. 800–770 Ma. As demonstrated by δO_{18} zircon data, the ca. 800–770
777 Ma protoliths of the VCC and PC metagneous rocks have crystallized in more evolved
778 magmas, either from the melting of host rocks and sediments or assimilation of crustal
779 material by mantle-derived magmas, as by assimilation-fractional crystallization (AFC)
780 process. Only a negligible number of zircon grains crystallized in equilibrium with
781 mantle-derived melts free of crustal contamination/assimilation. A connection between

782 the ca. 800-770 Ma protoliths of the Cerro Olivo Complex in southernmost Dom
783 Feliciano Belt and the high-grade rocks and metasediments of the VCC–PC basin is
784 supported by geochronological and zircon isotopic oxygen data presented in this study.

*Interpreted as recrystallization of the detrital grains during high-grade metamorphism.

** In spite of the fact that some grains are younger than 640 Ma, such data do not have any statistical meaning. Ca. 640 Ma was set as an age limit for the Neoproterozoic detrital zircon population, as this is the timing of the main metamorphic–deformational phase recorded in the hinterland of DFB (VCC and COC). The best metamorphic age for PMC is a Rb–Sr isochron in muscovite and whole-rock - 658 ± 26 Ma (Lenz, 2006).

*** The location of these samples is provided in table 2.

Dear Matheus Battisti,

Your manuscript entitled "Petrochronology of the central Dom Feliciano Belt foreland, southernmost Brazil" has been successfully submitted online and is being delivered to the Editorial Office of *Journal of Metamorphic Geology* for consideration.

You will receive a follow-up email with further instructions from our electronic editorial office platform, ScholarOne Manuscripts, typically within one business day. That message will confirm that the Editorial Office has received your submission and will provide your Manuscript ID.

Thank you for submitting your manuscript to *Journal of Metamorphic Geology*

Sincerely,
The Editorial Staff at Journal of Metamorphic Geology

By submitting a manuscript to or reviewing for this publication, your name, email address, and affiliation, and other contact details the publication might require, will be used for the regular operations of the publication, including, when necessary, sharing with the publisher (Wiley) and partners for production and publication. The publication and the publisher recognize the importance of protecting the personal information collected from users in the operation of these services and have practices in place to ensure that steps are taken to maintain the security, integrity, and privacy of the personal data collected and processed. Abstract:

The Dom Feliciano Belt is the South American part of an extensive Neoproterozoic orogenic system that developed during late Cryogenian–early Cambrian close to the margin of southwest Gondwana. P–T estimates, Lu–Hf garnet–whole-rock ages, U–Pb monazite SIMS ages and Y–REE garnet and monazite data from samples of the Porongos and Passo Feio complexes provide information about the tectonic evolution of the central Dom Feliciano Belt foreland. Metasedimentary rocks of the eastern Porongos Complex display a main metamorphic event at 662 ± 13 Ma (Lu–Hf isochron garnet–whole-rock age) and metamorphic peak conditions of ca. 560–580 °C, 5.8–6.3 kbar. This episode represents an early orogenic thickening event in the foreland as a response to the beginning of transpressive convergent evolution of the belt. The monazite age of 614 ± 6 Ma (U–Pb SIMS) is interpreted as associated with post-exhumation magmatic activity in the foreland and suggests that the eastern Porongos Complex was exhumed sometime between ca. 660 and 615 Ma. The main metamorphic and deformational event in the western region of Porongos Complex took place at ca. 550–570°C and 4.5–5.5 kbar at 563 ± 12 Ma (garnet–WR Lu–Hf isochron age). The exhumation of this part of the foreland is dated by using monazite crystalizing during garnet breakdown and suggests retrograde metamorphism at 541 ± 7 Ma (U–Pb SIMS). The main metamorphic fabric in the Passo Feio Complex further to the west developed at 571 ± 13 Ma (garnet–WR Lu–Hf isochron age) at metamorphic conditions of 560–580 °C and 4.7–6.4 kbar. The western part of the Porongos Complex and the Passo Feio Complex were deformed at similar PT conditions and apparent geothermal gradients at ca. 570–565 Ma. These regions record a second crustal thickening event in the Dom Feliciano Belt foreland and the orogenic front migration towards the west in a long-lived transpressive orogenic system.

Keywords: *Lu–Hf garnet–whole-rock dating, U–Pb monazite SIMS, crustal thickening, thermodynamic modelling, Dom Feliciano Belt*

1 1. INTRODUCTION

2
3 Determination of the timing of metamorphic events is critical for the correct
4 interpretation of the evolution of orogenic belts. In metamorphic terranes with
5 protracted evolution, separation of distinct deformation events from a progressive, but
6 single period of deformation is sometimes difficult due to the similar fabric
7 superposition and comparable changes in the metamorphic mineralogy. The
8 petrochronological approach (Fraser et al., 1997) combines the application of various
9 geochronometers with detailed petrological and microstructural observations in order
10 to accurately link the appearance of various mineral phases used for geochronology
11 with metamorphic–deformation events in a specific rock (Engi et al., 2017; Yakymchuk
12 et al., 2017). Due to different physical and chemical properties of each mineral and to
13 the specific closure temperature of their isotopic systems, various minerals such as
14 zircon (e.g. Rubatto et al., 2006), monazite (e.g. Rocha et al., 2017), garnet (Baxter et
15 al., 2017), titanite (Kohn, 2017), allanite, xenotime or apatite (Engi, 2017) can be
16 applied in petrochronological studies. Moreover, due to specific physical properties of
17 the datable minerals, it has become common to investigate more than one mineral
18 (and isotopic system) in the same rock in order to interpret the evolution of separate
19 geological units of metamorphic terranes in time (Hermann & Rubatto, 2003; Rubatto
20 et al., 2006; Stevens et al., 2015; Hagen-Peter et al., 2016; Regis et al., 2016; Rocha
21 et al., 2017; Schaltegger & Davies, 2017; Walczak et al., 2017; Konopásek et al., 2019;
22 Soret et al., 2019; Percival et al., 2022).

23 The Dom Feliciano Belt in SE South America (Fig. 1) is a case of a long-lived
24 Neoproterozoic belt built by protracted deformation. The complexity of its evolution is
25 highlighted by recent papers, which have suggested that the contractional period
26 lasted from ca. 660–650 Ma up to < ca. 570 Ma (e.g. Philipp et al., 2016; Oriolo et al.,
27 2016; Battisti et al., 2018; De Toni et al., 2020a, 2021; Percival et al., 2021, 2022;
28 Hueck et al., 2022). The main purpose of this paper is to determine the timing of critical
29 deformation events that shaped the present-day structure of the central Dom Feliciano
30 Belt. For this reason, two metamorphic complexes (Porongos and Passo Feio) of the
31 central Dom Feliciano Belt foreland were studied and compared. P–T estimates, Lu–
32 Hf garnet–whole-rock isochron ages and U–Pb SIMS monazite ages from
33 metasedimentary samples provided metamorphic and geochronological data, which
34 point at two separate and well-constrained periods of crustal thickening, followed by
35 periods of intense magmatic activity. The data provide evidence for progressive

36 migration of foreland deformation towards the west, away from the centre of the
37 orogenic system, and explain the recently discussed involvement of syn-orogenic
38 sediments and magmatic rocks in the deformation of the orogenic foreland (Battisti et
39 al., 2018 and submitted; Höfig et al., 2018).

40

41 **2. GEOLOGICAL SETTING**

42

43 **2.1 Dom Feliciano–Kaoko–Gariiep orogenic system**

44

45 The study area is located in the central Dom Feliciano Belt (Fig. 1 – DFB), which
46 is the South American part of a N-S trending Neoproterozoic orogenic system involving
47 also the Kaoko and Gariiep belts along the Atlantic coast of southern Africa. The Dom
48 Feliciano Belt is the result of the Brasiliano/Pan-African cycle which started at ca. 840–
49 800 Ma by igneous activity and associated sedimentation interpreted by some authors
50 as related to a continental arc (Koester et al., 2016; Martil et al., 2017; Battisti et al.,
51 2018; De Toni et al., 2020a) or as generated in a back-arc/rift setting (Konopásek et
52 al., 2018; Will et al., 2019). The system evolved into a contractional tectonic regime,
53 which started at ca. 660–650 Ma (e.g. Gross et al., 2006, 2009; Oyhantçabal et al.,
54 2009; Lenz et al., 2011; Martil, 2016; Peel et al., 2018; Will et al., 2019; De Toni et al.,
55 2020a; Konopásek et al., 2020; Percival et al., 2021, 2022). The contraction continued
56 until at least 580–550 Ma, as recorded by ongoing thickening and associated
57 metamorphism of both forelands of the orogenic system (Frimmel & Frank, 1998;
58 Goscombe & Gray, 2008; Höfig et al., 2018; Percival et al., 2022). Such convergent
59 period is related to the formation of the Gondwana supercontinent (e.g. Rapela et al.,
60 2011; Ramos et al., 2017; Oriolo et al., 2017).

61 Central DFB outcrops in southernmost Brazil (Rio Grande do Sul state) and is
62 usually divided into Western, Central and Eastern domains (Fragoso-Cesar et al.,
63 1986; Fernandes et al., 1992; Basei et al., 2000) (Fig. 1). The Western domain consists
64 of Paleoproterozoic rocks (2.5–2.0 Ga - Hartmann et al., 2000) of the foreland
65 basement, ophiolites reminiscent of an oceanic crust (920–890 Ma - Arena et al., 2016)
66 and juvenile arc-related rocks of the São Gabriel Block (750–690 Ma - Lena et al.,
67 2014) with associated metasedimentary complexes (as for example, the Passo Feio
68 Complex - Bitencourt, 1983).

69

70

71 Figure 1. A) Overview geological map and main tectonic domains of the Dom Feliciano–
 72 Kaoko–Gariép orogenic system (modified after Konopásek et al., 2018 and Bitencourt and
 73 Nardi, 2000). Relative position of Africa and South America is shown at 140 Ma - after Heine
 74 et al., 2013. Dom Feliciano Belt domains in the Rio Grande do Sul state are shown in the inset.
 75 Location of figure 2 is indicated. FL – Florianópolis, PA – Porto Alegre, MV – Montevideo.

76 The Central Domain is represented mainly by the Porongos Complex (PC)
77 composed of low- to medium-grade volcano-sedimentary rocks (Jost & Bitencourt,
78 1980; Saalman et al., 2005; Pertille et al., 2017) of Tonian to Ediacaran age (e.g.
79 Saalman et al., 2011; Pertille et al., 2017; Höfig et al., 2018; Battisti et al., submitted)
80 with locally exposed Paleoproterozoic basement (Encantadas Complex; 2.26–2.0 Ga
81 – Hartmann et al., 2003; Philipp et al., 2008). The foreland (Western and Central
82 domain) is extensively covered by late-orogenic, Ediacaran to Ordovician volcano-
83 sedimentary deposits (Oliveira et al., 2014; Paim et al., 2014).

84 The Eastern Domain represents the hinterland and in the Rio Grande do Sul state
85 it features mainly granitic rocks (also called Pelotas Batholith - Frago-Cesar et al.,
86 1986). The batholith is interpreted as part of a post-collisional granitic belt (Bitencourt
87 and Nardi 1993; Bitencourt and Nardi 2000; Philipp and Machado, 2002), whose
88 emplacement was controlled by a large-scale discontinuity (Southern Brazilian Shear
89 Belt - SBSB) active between ca. 650 and 580 Ma (Bitencourt & Nardi, 2000; Nardi &
90 Bitencourt, 2007). In Brazil, the Neoproterozoic granitic rocks contain roof pedants and
91 xenoliths of at least three distinct ages: Paleoproterozoic (2.2 and 2.0 Ga – Leite et al.,
92 2000; Gregory et al., 2015), Mesoproterozoic (ca 1.5 Ga – Chemale et al., 2011) and
93 Tonian (ca. 770–800 Ma - Koester et al., 2016; Martil et al., 2017, 2011). The most
94 extensive occurrence of the ca. 770–800 Ma rocks is the high-grade Várzea do
95 Capivarita Complex (VCC) (Fig. 1).

96

97 **2.2 Porongos Complex**

98

99 The Porongos Complex is a part of the Dom Feliciano Belt foreland and
100 comprises Neoproterozoic supracrustal rocks metamorphosed at lower greenschist to
101 middle amphibolite facies (Jost & Bitencourt, 1980; Saalman et al., 2006; Pertille et
102 al., 2017; Höfig et al., 2018; De Toni et al., 2021). The complex comprises
103 metasedimentary and metavolcanic rocks, some ultramafic lenses, and less often,
104 deformed granitic rocks (Jost & Bitencourt, 1980; Marques et al., 2003; Zvirtes et al.,
105 2017). Some authors interpret these ultramafic lenses as ophiolite remnants (Arena et
106 al., 2018; Werle et al., 2020). The PC metamorphic grade increases from west to
107 east. The Cerro do Facão staurolite-bearing metapelites at the easternmost border
108 (Fig. 2) record the highest metamorphic grade of the complex (Jost & Bitencourt, 1980;
109 Lenz, 2006). The peak PT conditions of these rocks were estimated at 560–580°C and

110 5.8–6.3 kbar (De Toni et al., 2021) and the only available metamorphic age is an
111 unpublished age of 658 ± 26 Ma (Lenz, 2006; Rb–Sr in muscovite and whole-rock).

112 Provenance studies in the PC have shown two distinct sources of the
113 metamorphosed clastic sediments (Gruber et al., 2011b, 2016b; Pertille et al., 2015b,
114 2015a, 2017; Höfig et al., 2018). Based on this data, Höfig et al. (2018) suggested that
115 the precursor of the Porongos Complex could have been at least two distinct and
116 diachronous basins. The older PC metasedimentary rocks (located mainly in the
117 eastern part – Fig. 2) represent mostly clastic infill of a pre-orogenic basin(s). The
118 younger PC basin is related to the syn-orogenic (< ca. 650 Ma) evolution, as discussed
119 by Höfig et al. (2018) and Battisti et al. (2018 and submitted). In the western part of the
120 PC (Fig. 2), the syn-orogenic sedimentary rocks are interleaved with the rocks of the
121 pre-orogenic PC basin(s) (Höfig et al., 2018). Ages of associated intermediate to acid
122 metavolcanic rocks also yielded contrasting ages in different regions of the complex.
123 Eastern regions of the PC contain metavolcanic rocks with protolith ages of ca. 770–
124 800 Ma (Saalman et al., 2011; Pertille et al., 2017; Battisti et al., submitted), whereas
125 studies of meta-volcanosedimentary rocks in the western portion of the complex (Höfig
126 et al., 2018) reported magmatic ages of ca. 600 and 601 Ma (LA–MC–ICP–MS, U–Pb
127 zircon). Such a dataset shows that the igneous activity and late sedimentation in the
128 northwestern PC are younger than the metamorphic peak recorded in the eastern
129 portion of the PC (658 ± 26 Ma - Lenz, 2006). According to the data compiled by
130 Battisti et al. (submitted – after authors quoted above), these two diachronous basins
131 are separated by the main W-verging thrust fault in the Porongos Complex called
132 Santana da Boa Vista thrust fault (Jost & Bitencourt, 1980). The metamorphosed pre-
133 orogenic sediments appear mostly east of the fault, whereas the rocks of the syn-
134 orogenic basin appear exclusively west of the fault.

135 Recent papers suggested that a part of the pre-orogenic basin of the PC and a
136 part of the Várzea do Capivarita Complex may have shared a similar sedimentary
137 depositional environment in their pre-collisional setting (Martil et al., 2017; Battisti et
138 al., 2018 and submitted). Battisti et al. (submitted) argued that both complexes share
139 igneous rocks with the same ca. 780 Ma protolith age and identical REE geochemistry,
140 similar isotopic Nd–Sr and oxygen signatures, similar structural evolution, and
141 convergent P–T–t evolution. These similarities led Battisti et al. (2018) and De Toni et
142 al. (2021) to conclude that the higher grade, deeper VCC hinterland rocks were thrust
143 over the lower grade, shallower PC foreland during a ca. 650 Ma collisional event.

144

 155 et al. (2003), Saalman et al. (2011), Gregory et al. (2015).

156

157 2.3 São Gabriel Block

158

159 The São Gabriel Block the largest occurrence of juvenile magmatic rocks in the
 160 DFB (e.g. Arena et al., 2017, 2016; Lena et al., 2014; Saalman et al., 2007, 2005).
 161 Although many authors do not consider the São Gabriel Block as part of the Dom
 162 Feliciano Belt and interpret it as a tectonic unit resulting from an independent orogeny
 163 (e.g. Chemale, 2000; Philipp et al., 2016b; Arena et al., 2017). there seems to be a
 164 consensus that its long-lived history also influenced the evolution of the DFB (Philipp
 165 et al., 2016; Konopásek et al., 2018; De Toni et al., 2020a).

166 According to Arena et al. (2016), some igneous rocks of the block may represent
167 part of an oceanic domain (ophiolites - 920–890 Ma), accreted to a juvenile arc (ca.
168 880 Ma Passinho event of Leite et al., 1998) that evolved towards a continental
169 magmatic arc (770–690 Ma - Lena et al., 2014). The oceanic closure is interpreted to
170 have happened between 690–650 Ma (Lena et al., 2014) or 650–600 (Arena et al.,
171 2017), whereas late granitic magmatism took place at ca. 585 Ma (Arena et al., 2017).
172 The São Gabriel Block structural framework features NE-striking planar fabrics,
173 predominantly dipping NW at low to medium angle, reworked by oblique, SE-verging
174 plus dextral transpression (Saalman et al., 2005).

175 Metagneous, arc-related rocks of the São Gabriel Block are surrounded by
176 metamorphic supracrustal complexes. The intrinsic characteristics of such complexes
177 (Pontas do Salso, Cambaí, Bossoroca, Imbicuí and Passo Feio - Philipp et al., 2021
178 and references therein) are beyond the scope of this work. The exception is the Passo
179 Feio Complex, introduced in detail.

180

181 **2.3.1 Passo Feio Complex**

182

183 The Passo Feio Complex is traditionally considered as the eastern-most unit of
184 the São Gabriel Block (Fig. 1, 2), separated from the easterly Porongos Complex by a
185 geophysical anomaly (Costa, 1997). However, the meaning of such anomaly is unclear
186 because its area is covered by post-orogenic sediments (Fig. 2). This has led some
187 authors to interpret the anomaly as a manifestation of a suture (Fernandes et al., 1995;
188 Costa, 1997); whereas others ((Costa et al., 2021), interpret it as a regional dextral
189 shear zone. As no further arguments are provided to confirm this magnetic anomaly
190 as a suture, the relation between the Passo Feio Complex and the rocks to the east
191 (Central and Eastern domains) remains uncertain, as does the eastern limit of the São
192 Gabriel Block.

193 The PFC comprises phyllites, metapelitic schists, amphibole-bearing rocks such
194 as amphibolites, metagabbros and amphibole schists, acid to intermediate
195 metavolcanoclastic rocks, and subordinate magnesian schists and marble lenses
196 (Bitencourt, 1983; Bitencourt & Hartmann, 1984a, 1984b; Costa et al., 2021). The PFC
197 outcrops as an antiformal structure with subhorizontal axis plunging either NNE or
198 SSW (Costa et al., 2021) with the 562 ± 8 Ma (SHRIMP U–Pb zircon - Remus et al.,
199 2000) calc-alkaline Caçapava Granite in its core. The PFC is surrounded by Ediacaran

200 to Ordovician volcano-sedimentary sequences of the Camaquã Basin (Oliveira et al.,
201 2014; Paim et al., 2014 - Fig. 2a), and in the northeast by the Parana Basin.

202 Three deformation events related to two metamorphic events were described in
203 the PFC (Bitencourt, 1983; Costa et al., 2021). The first two events are progressive
204 and coeval with the growth of garnet up to the peak metamorphic conditions (M_1). M_1
205 was estimated by Costa et al. (2021) at 560–570 °C and 5–5.5 kbar for a garnet–
206 staurolite schist and 500–510 °C and 5–6.4 kbar for a garnet phyllite. D_3 deformation
207 event and M_2 metamorphic event are closely related to the emplacement of the
208 Caçapava Granite (Bitencourt, 1983). According to Costa et al. (2021), the
209 crystallization of andalusite marks the effect of contact metamorphism caused by the
210 Caçapava Granite during M_2 – D_3 . S_3 has developed by folding of S_2 and locally displays
211 shear zones that drag S_2 with dextral shear sense. Regions where S_3 developed show
212 mainly recrystallization of biotite and relic minerals of M_1 , which indicates that M_2
213 reached intermediate greenschist facies (biotite zone) with pressures no higher than
214 ca. 4 kbar, as indicated by the crystallization of andalusite (Costa et al., 2021).

215 Geochronological data for the PFC first metamorphic event are rather limited and
216 obscure. A single SHRIMP spot in a zircon rim of 685 ± 12 Ma (Remus et al., 2000)
217 was associated with M_1 (which is probably a mixed age – see discussion). On the other
218 hand, the age of M_2 is better constrained as this metamorphism was interpreted
219 contemporaneous to the emplacement of the Caçapava Granite at ca. 562 Ma (see
220 above).

221

222 3. RESULTS

223

224 3.1 Sample description and estimates of metamorphic conditions

225

226 To quantify the metamorphic evolution of the Porongos and Passo Feio
227 complexes, the conditions of equilibration of mineral assemblages in three samples
228 (MAB51B, MAB56A and BD03) were modelled by calculating P–T pseudosections
229 based on the whole-rock chemical composition and H_2O component in excess. Due to
230 the absence of minerals with elevated content of Fe^{3+} , all Fe in the samples was
231 considered as FeO. The stability of the mineral assemblages was modelled using
232 *Perple_X* 6.8.9 software (Connolly, 2005, 2009) and thermodynamic properties of
233 mineral endmembers published by Holland and Powell (1998 – updated in 2004). The
234 mixing properties of the minerals were taken from Fuhrman and Lindsley (1988) for

235 feldspar and White et al. (2014) for biotite, white mica, chlorite, staurolite, chloritoid,
236 cordierite and garnet.

237 Whole-rock compositions were obtained from rock powder tablets using a Rigaku
238 RIX 2000 X-Ray Fluorescence analyser at the X-ray Fluorescence Laboratory of the
239 Universidade Federal do Rio Grande do Sul (UFRGS), Brazil and at AcmeLabs -
240 Bureau Veritas Minerals in Canada. Mineral compositions were determined at the
241 Microprobe Laboratory, CPGq, UFRGS, using the Cameca SXFive microprobe at
242 analytical conditions of 15 keV, 15 nA current, and beam size of 5 μm . The instrument
243 was calibrated using diopside (Ca, Mg), rhodonite (Mn), sanidine (Si, K, Al), Fe_2O_3
244 (Fe), albite (Na), rutile (Ti) and Cr_2O_3 (Cr) as standards. Mineral abbreviations used
245 through this paper are after Whitney and Evans (2010).

246

247 **3.1.1 MAB51B – Eastern region of the Porongos Complex**

248

249 Sample MAB51B (30.73782° S, 52.81326° W – all coordinates in WGS84) is a
250 garnet-plagioclase-biotite-muscovite schist (Fig. 3a, b) collected in the eastern part of
251 the Porongos complex, in the hanging wall of the Santana da Boa Vista thrust fault.
252 The schistosity is marked by lepidoblastic muscovite (ca. 65 vol.%) and biotite (ca. 15
253 vol.%). Both types of mica form crystals up to 0.5 mm long and commonly display
254 isoclinal micro folds and undulose extinction. Muscovite contains 3.06–3.20 atoms per
255 formula unit (a.p.f.u.) of Si and 0.02 a.p.f.u. of Ti. Biotite shows $X_{\text{Mg}} = (\text{Mg}/(\text{Mg} + \text{Fe}^{2+}))$
256 of 0.47–0.49, 0.09 a.p.f.u. of Ti and 1.27–1.33 of Al^{IV} (Table 1 and supplementary data).
257 Plagioclase (ca. 8 vol.%), quartz (ca. 2 vol.%), and accessory K-feldspar ($\ll 1$ vol.%)
258 appear in lenses with fine-grained (0.06–0.2 mm) inequigranular texture. Garnet (ca. 5
259 vol.%) forms 3-4 mm large isometric grains, usually with well-developed crystal faces
260 and internal cracks. The grains show very weak chemical zoning with slight increase
261 in pyrope (Prp) and almandine (Alm) components from core to rim, compensated by a
262 decrease in grossular (Grs) and spessartine (Sps) components. General garnet core-
263 to-rim composition (mol.%) is Alm_{53-58} , Prp_{6-7} , Grs_{10-8} , Sps_{31-27} . The X_{Mg} value of 0.10–
264 0.11 is almost constant across the entire crystal. Chlorite (ca. 3 vol.%) has X_{Mg} of 0.50–
265 0.53 and forms isolated, ca. 1 mm long individual clusters interpreted as late
266 overgrowths on muscovite-biotite crystals. Rare tiny staurolite crystals (<0.05 mm, $\ll 1$
267 vol.%) were found by SEM. A sample nearby (see fig. 7b in De Toni et al., 2021)
268 suggests the presence of staurolite completely replaced by muscovite (Fig. 3c). The
269 main opaque phase is ilmenite (ca. 1 vol.%).

270 P–T pseudosection calculated for sample MAB51B (Fig. 4, bulk composition in
271 mass proportions: SiO₂ – 42.05; Al₂O₃ – 30.37; TiO₂ – 1.41; FeO – 6.53; MnO – 0.29;
272 MgO – 2.92; CaO – 0.20; Na₂O – 0.59; K₂O – 8.69) indicates that the assemblage Chl
273 + Grt + Ms + Bt + Pl + Qz + Ilm is stable approximately at 470–560°C, and in a pressure
274 range below 5.0 kbar. The isopleths calculated for endmember proportions in the
275 garnet core revealed pre-peak conditions of 515–535°C and 3.4–4.4 kbar. Isopleths
276 for garnet rim endmembers suggest equilibration with the matrix at 530–550°C and
277 3.6–4.5 kbar. Although biotite is locally replaced by chlorite in the sample MAB51B, its
278 observed X_{Mg} values agree with those for estimated metamorphic conditions of the
279 matrix assemblage. The incipient crystallization of staurolite (only observed in SEM
280 images) suggests the peak metamorphic conditions close to the staurolite-in reaction,
281 which is modelled at ca. 10 to 15°C higher than the peak metamorphic conditions
282 estimated by isopleths at 3.6 and 4.5 kbar, respectively. For this reason, the best
283 estimate for the metamorphic peak of this sample is 530–565°C and 3.6–4.5 kbar.
284 Comparison of the observed vs. modelled mineral compositional parameters from all
285 studied samples is shown in table 2.

The pink polygon shows the area where isopleths of the garnet core cross (see details in bottom-right P–T diagram).

307 3.1.2 MAB56A – Northwestern region of the Porongos Complex

308

309 Sample MAB56A (30.4767° S; 52.9818° W) is a garnet-bearing plagioclase–
310 biotite–quartz–muscovite schist (Fig. 5) from the northwestern part of the Porongos
311 Complex, where the pre-orogenic metasedimentary rocks were tectonically interleaved
312 with the syn-orogenic flysch sediments (Höfig et al., 2018; Battisti et al., submitted).
313 The sample was collected in the structural footwall of the Santana da Boa Vista thrust
314 fault. The schistosity is marked by an alternation of muscovite-rich and quartz-
315 plagioclase-rich layers, both intensely microfolded. The lepidoblastic texture and shape
316 preferred orientation of muscovite (ca. 40 vol.%) with crystal sizes up to 2 mm mark
317 the main schistosity. Muscovite contains 2.98–3.08 a.p.f.u. of Si and 0.02–0.04 a.p.f.u.
318 of Ti. Quartz and plagioclase are fine-grained (up to 0.4 mm) and display lenses with
319 intergranular interlobate texture. Together, Qz and Pl make ca. 45% of the rock
320 volume. Plagioclase is albite (An_{0–2}) with <1 mol.% of K-feldspar component. Biotite
321 (ca. 10 vol.%) crystals are up to 0.5 mm long with lepidoblastic texture in mica-rich
322 layers. Biotite shows X_{Mg} between 0.31 and 0.35, 0.09–0.16 a.p.f.u. of Ti and 1.32–
323 1.45 of Al^{IV}.

324 Garnet (ca. 3 vol.%) forms mostly equant, up to 5 mm large porphyroblasts,
325 usually cracked and partly consumed along the edges. They rarely show sigmoidal
326 quartz and ilmenite inclusion trails that mark the porphyroblast rotation relative to the
327 external matrix foliation during growth (Fig. 5c). In the fractures, chlorite commonly
328 grows due to garnet dissolution (Fig. 5 and 12). We interpret the garnet as a relic
329 mineral phase in the sample, otherwise subject to severe retrogression. Garnet grains
330 show strong chemical zoning with increasing pyrope and almandine components from
331 core to rim compensated by a decrease in grossular and spessartine components.
332 General garnet core-to-rim composition (mol.%) is Alm_{67–82}, Py_{5–10}, Grs_{12–6}, Sps_{16–2}.
333 The X_{Mg} value increases from 0.07 to 0.11 from core to rim (Table 1, 2).

334 Chlorite (ca. 2 vol.%) crystals are up to 0.3 mm long, and they occur as both
335 dispersed in the rock matrix and in cracks and pressure shadow tails of garnet
336 porphyroblasts. Chlorite X_{Mg} varies from 0.37 to 0.43. Chlorite is interpreted to have
337 formed after the metamorphic peak by a retrogressive reaction that consumed garnet
338 and some biotite in the matrix. Accessory minerals are tourmaline, apatite, monazite,
339 and zircon.

340

341

342

343 Figure 5. MAB56A garnet-bearing plagioclase–biotite–quartz–muscovite schist. A) general
 344 view of the rock microstructure with detail of a relic of strongly dissolved garnet crystal. B, C)
 345 Representative mineral chemistry of garnet indicated by colored dots. Location of SEM images
 346 presented in Figs 12e and f are indicated.

347

348 P–T pseudosection calculated for sample MAB56A (Fig. 6, bulk composition in
 349 mass proportions: SiO₂ – 62.15; Al₂O₃ – 18.34; TiO₂ – 1.11; FeO – 8.14; MnO – 0.14;

350 MgO – 1.96; CaO – 0.89; Na₂O – 0.45; K₂O – 3.23) indicates that the matrix
351 assemblage Chl + Grt + Ms + Bt + Qz + Pl + Ilm is stable approximately at 490–560°C,
352 and in the pressure range of 1.5 to 5.3 kbar. However, garnet grains represent relics
353 of larger porphyroblasts consumed by retrograde reactions. Such observation
354 suggests that rims of the least re-equilibrated porphyroblasts that survived the
355 retrogression may represent higher metamorphic conditions than the matrix
356 assemblage itself. Isoleths for such garnet rim compositions overlap in an interval of
357 550–570°C at 4.5–5.5 kbar, reaching even the staurolite stability field (field 24 – figure
358 6). Thus, staurolite might have been present at the metamorphic peak and then all
359 consumed during retrogression. The isopleths calculated for the garnet core
360 composition revealed conditions of 520–540°C and 3.9–5.3 kbar for the early garnet
361 growth.

362 Based on petrological evidence, chlorite in the sample MAB56A grew during the
363 retrograde breakdown of garnet. Therefore, five chlorite analyses were performed by
364 EPMA to apply chlorite geothermometers and retrieve information about retrograde
365 metamorphic temperature (Fig. 7). For the geothermometers of Cathelineau (1988),
366 Cathelineau and Nieva (1985) and De Caritat et al. (1993) we assumed $Fe_{total}=FeO$,
367 and the temperatures were calculated using the software of Yavuz et al. (2015). When
368 applying the geothermometer of Vidal et al. (2001), two estimates were made, one
369 assuming $Fe_{total}=FeO$, and the other considering the presence of Fe^{3+} based on the
370 calculations described in Vidal et al. (2001). The obtained results vary from ca. 250 to
371 ca. 500°C. Using the mean calculated temperatures with 1σ standard deviation for all
372 values calculated by the six different methods as indicated in figure 7, the most
373 probable temperature of chlorite formation is considered between ca. 310–440°C.
374

375

376

377

378 Figure 6. P–T pseudosection calculated for the sample MAB56A. Metamorphic conditions for

379 the early garnet growth (pink polygon) and for the garnet rim stability (blue polygon) were

380 estimated only from the observed garnet chemistry, because the mineral assemblage of the

381 matrix is interpreted as not reflecting the peak metamorphic conditions (see text for

382 explanation). Isopleths for garnet rim and core compositions are presented in P–T diagrams

383 at the bottom of the figure.

384

385

386 Figure 7. Estimated temperature of retrograde chlorite growth in sample MAB56A based on
 387 some commonly applied geothermometers. Considering all individual calculations from all
 388 geothermometers, the best estimated temperature for chlorite growth appears between 438–
 389 308 °C (mean ± 1σ). Temperature estimates by each geothermometer are the following:
 390 439±39 °C not considering Fe³⁺ and 408±38 °C considering Fe³⁺ (Vidal et al., 2001); 418±38
 391 °C using Si^{IV} occupancy and 295±9 °C using Al^{IV} occupancy (De Caritat et al., 1993); 379±7 °C
 392 (Cathelineau, 1988); 304±5 °C (Cathelineau & Nieva, 1985).

393

394 3.1.3. BD03 - Passo Feio Complex

395

396 Sample BD03 (30.64389° S; 53.45345° W) is a muscovite–garnet–staurolite–
 397 biotite–plagioclase–quartz schist (Fig. 8) collected in the southern part of the Passo
 398 Feio Complex (Fig. 2). The schistosity is marked by alternating mica-rich and quartz-
 399 rich layers (Fig. 8a). Mica-rich layers are discontinuous, up to 1 mm thick and
 400 composed of lepidoblastic biotite (ca. 25 vol.%) and muscovite (ca. 5 vol.%) up to 1.5
 401 mm in length, and locally chlorite (ca. 1 vol.%). Muscovite contains 3.02–3.04 a.p.f.u.
 402 of Si and 0.02 a.p.f.u. of Ti, whereas biotite shows X_{Mg} between 0.44–0.51, 0.04–0.09
 403 a.p.f.u. of Ti and 1.26–1.32 of Al^{IV}. Chlorite has X_{Mg} of 0.51–0.53. Quartz-rich layers
 404 also contain some fine-grained (0.05 to 1 mm) plagioclase with inequigranular seriate
 405 texture (both adding up to ca. 45 vol.%). Plagioclase is andesine (An_{32–34}) with <1

406 mol.% of K-feldspar component. The opaque phase is ilmenite and represents ca. 2
407 vol.%.

408 The external foliation wraps around the garnet and staurolite porphyroblasts and
409 their pre- to syn-tectonic origin is suggested by the rotation of their internal foliation
410 highlighted by opaque minerals and quartz inclusions (Fig. 8b). Staurolite
411 porphyroblasts (ca. 15 vol.%; $X_{Mg} = 0.16\text{--}0.20$) are up to 3.5 mm large and appear
412 mostly in the mica-rich layers. Garnet (ca. 8 vol.%) forms 0.8–1.5 mm large equant
413 grains, usually with internal cracks (Fig. 8c). Such grains usually contain quartz, and
414 opaque mineral inclusions and pressure shadows made up of biotite, muscovite, and
415 quartz. Garnet grains show a strong chemical zoning with increasing almandine
416 component from core to rim compensated by a decrease of spessartine component.
417 On the other hand, grossular and pyrope display a very weak chemical zoning. General
418 garnet core-to-rim composition (mol.%) is $Alm_{65\text{--}75}$, $Prp_{7\text{--}11}$, $Grs_{8\text{--}6}$, $Sps_{20\text{--}8}$. The $X_{Mg} =$
419 $0.10\text{--}0.13$ is almost constant from core to rim. Accessory phases are represented
420 mainly by ilmenite, tourmaline and zircon.

421 P–T pseudosection calculated for sample BD03 (bulk composition in mass
422 proportions: $SiO_2 - 64.13$; $Al_2O_3 - 15.61$; $TiO_2 - 0.96$; $FeO - 7.95$; $MnO - 0.12$; MgO
423 $- 3.13$; $CaO - 1.53$; $Na_2O - 1.81$; $K_2O - 2.60$) is presented in figure 9. The estimate of
424 peak metamorphic conditions has been made using garnet fractionation routine
425 available in the *Perple_X* software. The reason for the subtraction of garnet interior
426 from the bulk is that the garnet shows strong chemical zonation from core to rim, which
427 together with its high modal proportion (ca. 8 vol.%) may influence the effective
428 composition available during peak metamorphic conditions (Lanari & Engi, 2017).
429 Garnet core conditions were established at 525–545°C and 4.1 – 4.5 kbar (Fig. 9a)
430 without applying the fractionation routine (Table 2). Several fractionation paths with
431 different slopes in the PT space were tested (always crossing the garnet core
432 conditions) to find out PT conditions at which the modelled final garnet composition
433 successfully reproduced the observed composition of the garnet rim in the sample.
434 Four fractionation paths met such condition and all of them led to similar results (Fig.
435 9b), which indicate that the assemblage $Chl + Grt + Ms + St + Bt + Pl + Qz + Ilm$ was
436 stable at ca. 560–600°C and above 4.7 kbar (Fig. 9). Isopleths for garnet rim
437 endmembers, in addition to X_{Mg} in staurolite and biotite, and X_{An} in plagioclase, suggest
438 equilibration conditions at 560–580°C and 4.7–6.5 kbar.
439

440

441

442

Figure 8. BD03 muscovite–garnet–staurolite–biotite–plagioclase–quartz schist. A) General view of the rock microstructure; B) Syn-kinematic staurolite porphyroblast; C) Detail of a garnet porphyroblast. Photomicrographs were taken in both plane-polarized (PPL) and cross-polarized light (XPL) to highlight textural aspects of the rock.

446

447

448 Figure 9. Calculated P–T pseudosections for the sample BD03. A) Phase diagram calculated
 449 for the bulk chemistry of the sample. Various paths tested during utilization of the fractionation
 450 routine are indicated by dashed sub-horizontal black lines connecting the colored fields
 451 delimiting estimated P–T conditions for garnet core and rim compositions. b) Phase diagram
 452 calculated for the bulk rock chemistry modified by gradual removal of corresponding garnet
 453 volume and composition along the selected fractionation path (white dashed line). Although
 454 the P–T conditions of stabilization of the matrix mineral assemblage are similar in both
 455 diagrams, the P–T diagram for fractionated bulk rock composition shows better match of the
 456 mineral composition with the peak metamorphic assemblage field (field 23 in A, and field 19 in
 457 B).

458 **3.2 Lu–Hf garnet geochronology and trace elements chemistry**

459

460 Lu–Hf garnet–whole-rock isochron ages were obtained for three samples to
461 provide a temporal framework for the studied metamorphic evolution of the central
462 Dom Feliciano Belt foreland (Table 3, figure 10). In addition, Y–REE and additional
463 trace elements (Hf, U, Ti, Nd – see supplementary file) were analysed along transects
464 across garnet to determine the potential influence of inclusions on bulk mineral
465 separate isotopic systematics, and the influence of zonation on age interpretation. The
466 results of trace element analysis are summarized in figures 11, 12 and 13, and
467 complete data are available in supplementary files. Complete analytical methods for
468 the Lu–Hf isotopic dating are described in appendix 1. Standards reproducibility and
469 constants used for the Lu–Hf isochron calculations are given in the footnote to Table
470 3.

471

472 **INSERT TABLE 3**

473

474 **3.2.1 MAB51B – Eastern region of the Porongos Complex**

475

476 Lu–Hf isotopic analysis of sample MAB51B yielded a garnet–whole-rock isochron
477 age of 662 ± 13 Ma, based on six garnet aliquots and two representative whole-rock
478 powder aliquots (Fig. 10a).

479 Rim-to-rim profiles of two garnet crystals in this sample were analysed for Y–REE
480 and trace element contents. The Y–REE data present an almost homogeneous pattern
481 for all analysed spots (Fig. 11a). The data demonstrate a well-known (e.g. Hacker et
482 al., 2019; Rubatto et al., 2006) enrichment of Heavy Rare Earth Elements (HREE –
483 10^2 to 10^3 ppm) over Light Rare Earth Elements (LREE – 10^{-3} to 10^1 ppm). Although
484 garnet cores are somewhat enriched in LREE compared to garnet rims, and HREE
485 concentrations increase slightly towards the rims, this variation is negligible. The data
486 in figure 11 also indicate a negligible europium anomaly $\text{Eu}/\text{Eu}^* [(\text{Eu}_{\text{norm}})/(\text{Sm}_{\text{norm}} \times$
487 $\text{Gd}_{\text{norm}})^{0.5}]$ ranging from 0.26 to 0.60, for garnet 1 and 0.24 to 0.60, for garnet 2 (see
488 details in supplementary file).

489 The Lu profile is rather flat, with only a slightly higher concentration in the garnet
490 core and an anomalous enrichment in the right-hand outermost rim (Fig 12a). Hf shows
491 peaks that coincide with peaks in U suggesting the presence of zircon inclusions.
492 Presence of ilmenite inclusions is also indicated by peaks of Ti (Fig. 12a). Considering

493 the clean part of garnet (without mixed analyses from mineral inclusions), Lu shows a
 494 mean value of 30 ppm and Hf 1 ppm. All isotopic and trace element data are available
 495 as supplementary material.

502

503 Figure 11. REE data for garnet (A) and monazite (B) in sample MAB51B, normalized to
 504 chondrite (Boyton, 1984). In (A), color coding of the REE curves indicates the distance of each
 505 analytical spot from the garnet center. (C) BSE images showing textures of analysed monazite
 506 grains and their respective U^{238}/Pb^{206} dates. (D) U–Pb SIMS concordia age of monazite
 507 calculated from all analysed grains. In (B) and (D), color-coded REE curves and ellipses
 508 distinguish each SIMS spot in monazite grains shown in (C). Textural relationship of monazite
 509 with other mineral phases in the thin section are illustrated in BSE images in (E), (F) and (G).
 510 Additional trace element data and garnet laser spots are presented as supplementary material.

511

512

513 Figure 12. Lu–Hf–U–Ti–Nd curves from garnet of MAB51B (a – grt1) and MAB56A (b – grt3)

514 – Porongos Complex; and garnet of BD03 (c – grt5) – Passo Feio Complex. The colored bars

515 indicate presence of inclusions.

516

517

518 **3.2.2 MAB56A – Northwestern region of the Porongos Complex**

519

520 Lu–Hf isotopic analysis of six garnet aliquots and two representative whole-rock
521 powder aliquots yielded a garnet–whole-rock isochron age of 563 ± 12 Ma for sample
522 MAB56A (Fig. 10b).

523 Two crystals (garnet 3 and 4) were selected for Y–REE data acquisition in thin
524 section by LA–ICP–MS. The REE patterns show mild enrichment in LREE of the rim
525 over the core, whereas the core is strongly enriched in HREE. Eu/Eu* values for garnet
526 3 range from 0.69 to 1.56, and from 0.59 to 0.78 for garnet 4 (Fig 13a).

527 Garnet 3 presents complex zoning of Lu with several peaks in different crystal
528 growth zones (Fig. 12b). Several Hf+U peaks suggests presence of zircon inclusions,
529 whereas inclusions of ilmenite are evident from numerous peaks in Ti. In the clean
530 garnet Lu shows a mean value of 5 ppm and Hf 2 ppm.

531

532 **3.2.3 BD03 – Passo Feio Complex**

533

534 For sample BD03, Lu–Hf isotopic analysis of five garnet aliquots and two
535 representative whole-rock powder aliquots yielded a garnet–whole-rock isochron age
536 of 571 ± 13 Ma (Fig. 10c).

537 The analysed garnet in sample BD03 (garnet 5) displays a general enrichment in
538 Lu towards the right-hand side of the crystal (Fig. 12c). The appearance of Hf+U, Ti
539 and U+Nd peaks suggests the presence of zircon, ilmenite and monazite/allanite
540 inclusions, respectively. Lu shows a mean value of 6 ppm and Hf 1 ppm in the regions
541 not affected by inclusions.

542

543

544 Figure 13. REE data for garnet (A) and monazite (B) in sample MAB56A), normalized to
 545 chondrite (Boyton, 1984). In (A), color coding of the REE curves indicates the distance of each
 546 analytical spot from the garnet center. (C) BSE images showing textures of analysed monazite
 547 grains and their respective U^{238}/Pb^{206} dates. (D) U–Pb SIMS concordia age of monazite
 548 calculated from all analysed spots. In (B) and (D), color-coded REE curves and ellipses
 549 distinguish each SIMS spot in monazite grains shown in (C). Textural relationship of monazite
 550 with other mineral phases in the thin section are illustrated in BSE images in (E) and (F).
 551 Additional trace element data and garnet laser spots are presented as supplementary material.

552 3.3 U–Pb SIMS monazite geochronology and trace elements chemistry

553

554 Monazite crystals were separated from samples MAB51B and MAB56A, whilst
555 no monazite was found in sample BD03. The monazite age was determined by U–Pb
556 isotopic dating using the Secondary Ion Mass Spectrometry (SIMS) at the NORDSIM
557 facility hosted by the Swedish Natural History Museum in Stockholm. Y–REE data for
558 monazite were acquired by LA–ICP–MS in individual monazite grains (in mount – near
559 spots previously analysed for U–Pb age dating) to compare their chemistry with that of
560 garnet. These data were completed by concentration maps for selected trace elements
561 to understand their spatial distribution in the analysed grains. Details of both separation
562 and analytical methods are provided in appendix 1.

563

564 3.3.1 MAB51B – Eastern region of the Porongos Complex

565

566 Monazite extracted from sample MAB51B forms irregular grains up to 200 μm
567 large, which display various zoning patterns (Fig. 11). Most grains show well-preserved
568 sector or oscillatory zoning; however, zoning in some grains is more complex. SEM
569 imaging of monazite crystals in the thin section revealed either single crystals in the
570 matrix (Fig. 11e, f), or grains apparently crystallized during the replacement of some
571 other mineral (Fig. 11g).

572 Seventeen SIMS isotopic analyses were performed in thirteen different
573 monazite grains and the resulting data are plotted in a conventional Wetherill U–Pb
574 concordia diagram. Considering all data, the 17 spots yielded a pooled concordia age
575 of 614 ± 6 Ma (2σ), which we consider as the age of crystallization of monazite in the
576 sample (Fig. 11d).

577 REE data normalized to chondrite (Boyton, 1984) show enrichment of LREE
578 over HREE (Fig. 11b). A pronounced Eu/Eu* anomaly ranges from 0.007 to 0.040.
579 Th/U ratios of the grains range between 13.3 to 46.2, with one outlier of 70.8.

580

581 3.3.2 MAB56A – Northwestern region of the Porongos Complex

582

583 Monazite separated from sample MAB56A is up to 200 μm large (Fig 13). The
584 crystals are usually rounded and cracked and display weak zoning. Concentric zoning
585 is observed in some crystals and two crystals preserve a central part rich in inclusions
586 with a darker color. In the thin section, monazite is found in garnet cracks together with

587 chlorite (Fig 13e, f), which suggests that monazite growth is closely related to the
588 destabilization of garnet during retrogression.

589 Sixteen SIMS isotopic analyses were performed in eleven monazite grains of
590 the sample. The data were plotted in the Wetherill U–Pb concordia diagram (Fig 13d)
591 and yielded a pooled concordia age of 541 ± 7 Ma (2σ).

592 REE data of monazite normalized to chondrite (Boyton, 1984) show enrichment
593 of LREE over HREE (Fig. 13a). Although the LREE concentration is rather
594 homogeneous in all analysed grains, they show a strong variation in HREE content. A
595 small Eu/Eu* anomaly ranges from 0.36 to 0.63). Th/U ratios range between 3.3 and
596 26.0.

597

598 **4. Discussion**

599

600 **4.1. Garnet and monazite petrochronology**

601

602 **4.1.1. MAB51B – Metamorphic peak in the eastern Porongos Complex (ca. 660** 603 **Ma)**

604

605 In sample MAB51B, garnet displays a homogenous REE pattern for both rim and
606 core suggesting equilibrium with stable minerals in the matrix during its growth (Lanari
607 and Engi, 2017). Furthermore, the weak Eu anomaly recorded by the garnet (Eu/Eu*
608 0.24 to 0.60) likely suggests its growth in equilibrium with the matrix plagioclase. The
609 Lu–Hf isochron age suggests that the metamorphic event responsible for the growth
610 of garnet took place at 662 ± 13 Ma.

611 Trace element data suggest mild enrichment of Lu in garnet core (Fig. 12a). In
612 metamorphic rocks, Lu usually shows partitioning into garnet core relative to rims due
613 to Rayleigh fractionation. Consequently, the Lu–Hf bulk garnet age is biased towards
614 an early garnet growth (e.g. Baxter and Scherer, 2013). In our case, the weak Lu
615 enrichment in the centre of the profile either means that this element is more
616 homogeneously distributed than in typical prograde garnet, or that the analysed section
617 did not reach the very core of the crystal. Thus, the above-reported garnet age should
618 be considered as an average age for garnet growth in the sample MAB51B. The mean
619 Hf content acquired by LA–ICP–MS analysis of clean garnet (1 ppm) presents
620 discrepancy when compared to the value found from garnet isotope dilution (4 ppm –
621 Table 3). This disparity is likely attributed to contamination from Hf-rich accessory

622 mineral inclusions in garnet. The presence of micro-inclusions of zircon and ilmenite in
623 garnet is confirmed by spikes in U+Hf and Ti respectively in figure 12. Despite efforts
624 to reduce the presence of such inclusions in garnet (after Anczkiewicz et al., 2004)
625 some Hf-rich inclusions may have dissolved together with the garnet. Although, a huge
626 Hf contamination, as the case of zircon inclusions, would swipe off the isochron, which
627 seems not the case, as all analyses stay aligned. Thus, it is most likely the Hf
628 contamination was generated by some other 'low-Hf' mineral than zircon, as for
629 example ilmenite, which would not pose any problems to the age estimates. This age
630 estimate overlaps within error with an unpublished Rb–Sr white mica/whole-rock age
631 of 658 ± 26 Ma from the same region (Lenz, 2006).

632 The peak conditions of the metamorphic event responsible for garnet growth
633 estimated by thermodynamic modeling were calculated at ca. 530–565°C and 3.6–4.5
634 kbar (Fig. 4). This estimate is ca. 15°C lower than the maximum temperature
635 suggested by De Toni et al. (2021). Pressure estimates by De Toni et al. (2021) and
636 Lenz (2006) range from 5.4 to 6.3 kbar, which is ca. 1–2 kbar more than found in
637 MAB51B (Table 4). However, both authors worked with staurolite-rich samples from
638 an outcrop ca. 100 m away from the location of MAB51B, and it is likely that those
639 rocks reached somewhat higher metamorphic grade.

640

641 **4.1.2. MAB51B – Exhumation of the eastern Porongos Complex (ca. 615 Ma)**

642

643 Monazite in sample MAB51B displays a generally homogenous REE pattern, with
644 only a small spread in the HREE content for individual grains. Such variation in HREE
645 can be either interpreted as local heterogeneities in rock chemistry or as a time-related
646 HREE zoning. The first possibility seems to be more likely, as the individual U–Pb
647 dates form a homogeneous cluster in the concordia diagram (Fig. 11d). Thus, we
648 interpret that all the analysed monazite grains represent the same event of monazite
649 growth and the observed HREE variation may reflect a variable availability of HREE in
650 the rock.

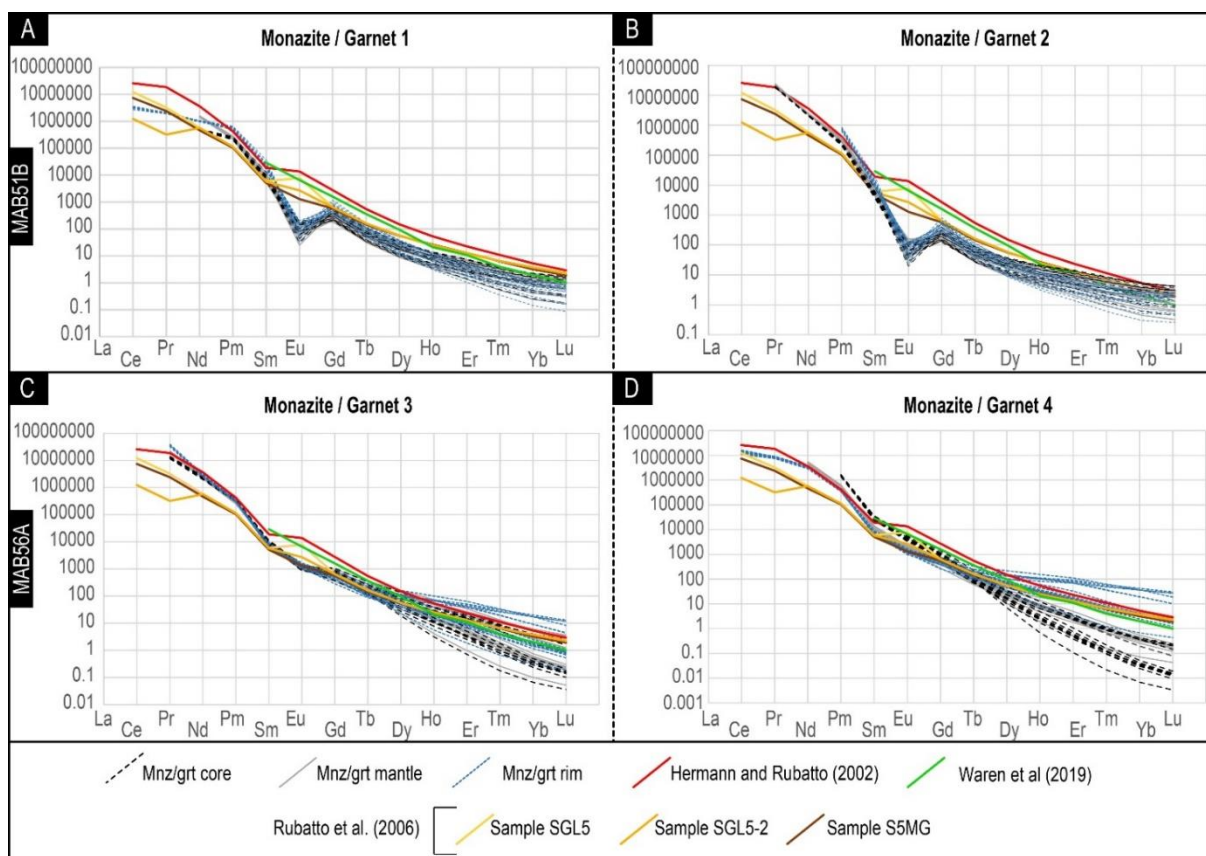

651 Monazite grains in this sample present an extremely pronounced Eu anomaly
652 ($\text{Eu}/\text{Eu}^* = 0.040$ to 0.007). Usually, such highly negative Eu anomaly is interpreted to
653 represent monazite growth in equilibrium with plagioclase during melt crystallisation
654 (Rubatto et al., 2006; Johnson et al., 2015; Hagen-Peter et al., 2016). This is also a
655 common situation in high-grade, migmatitic metamorphic rocks (e.g. Rubatto et al.,
656 2013; Johnson et al., 2015; Hagen-Peter et al., 2016), but clearly not the case for our

657 lower-amphibolite facies schist. Moreover, the Eu anomaly in monazite is much
658 stronger than that found in the garnet of the same sample (Fig. 11a, b), suggesting that
659 the monazite did not grow during the garnet-forming metamorphic event (e.g. Rubatto
660 et al., 2006).

661 Calculated distribution coefficients of REE between monazite and garnet (Fig.
662 14a, b) may be used as another proxy for interpreting the mutual stability of these two
663 minerals during their growth. Kd curves were calculated for the REE content of each
664 analytical spot in monazite divided by REE content of one representative spot for each
665 garnet region (core, mantle and rim; for values see supplementary data file). The Kd
666 values for garnet 1 (Fig 14a) and garnet 2 (Fig 14b) of sample MAB51B show similar
667 results for all three garnet regions. Although, the LREE distribution coefficients are in
668 the range expected for equilibrium growth by previous studies (Hermann & Rubatto,
669 2003; Rubatto et al., 2006; Warren et al., 2019), the MREE and HREE present lower
670 (to much lower – e.g. Eu) distribution coefficients than expected for monazite which
671 would crystallize in equilibrium with garnet. Such results may be seen as another
672 indication that garnet and monazite in sample MAB51B did not crystallize in
673 equilibrium.

674 All the data presented and discussed above point to a monazite-forming event
675 postdating the metamorphic peak reached by the schists of the eastern Porongos
676 Complex. A significant activity of fluids altering the peak metamorphic assemblage is
677 widespread in the region of sample MAB51B, as documented by muscovite halos
678 replacing staurolite crystals and growth of andalusite crystals up to 10 cm in size in
679 staurolite schists of the region (Lenz, 2006; De Toni et al., 2021), or by the high density
680 of quartz veins close to the nearby Passo do Marinheiro Fault. Thus, we interpret the
681 large Eu anomaly found in the dated monazite from this sample as reflecting growth of
682 the crystals triggered by Eu-depleted fluids. The best candidates for releasing such
683 fluids are the nearby magmatic rocks. The Encruzilhada Granite is the closest, however
684 it assimilates ca. 580 Ma syenitic rocks (Padilha et al., 2019), and thus, it is too young
685 to be the fluid source. On the other hand, the ca. 609 Ma pulse of the multiphase Piquiri
686 Syenite Massif (Rivera, 2016; Sbaraini et al., 2020), which has also caused local
687 contact metamorphism in PC rocks (Battisti et al., 2018), is the most likely candidate
688 for the fluid source. K-feldspar may show a stronger positive anomaly than plagioclase
689 (Bea et al., 1994), and feldspar-rich magmatic rocks tend to concentrate Eu in the
690 primary feldspar (Larsen, 2002; Gahlan et al., 2016), which in turn may lead to the
691 release of strongly Eu-depleted fluid during their crystallization. Therefore, we interpret

692 the ca. 615 Ma monazite crystals as dating the time of release of fluids from
 693 crystallizing syenitic rocks in the close vicinity. Furthermore, we associate the monazite
 694 growth with other features, e.g., the post-kinematic growth of andalusite or replacement
 695 of staurolite by muscovite coronas (De Toni et al., 2021). Together with the Lu-Hf
 696 garnet age, these features suggest that the eastern Porongos Complex was exhumed
 697 between ca. 660–615 Ma.
 698

699
 700

701 Figure 14. Calculated distribution coefficients of REE between: A) monazite and garnet 1 and
 702 B) monazite and garnet 2 in sample MAB51B, and C) monazite and garnet 3 and D) monazite
 703 and garnet 4 in sample MAB 56A. Dashed black lines: Mnz/Grt core, gray lines: Mnz/Grt
 704 mantle, dashed blue lines: Mnz/Grt rim.

705

706 **4.1.3. MAB56A – Metamorphic peak in the northwestern Porongos Complex (ca.** 707 **560 Ma)**

708

709 In sample MAB56A, relict garnet grains present a systematic variation of HREE
 710 content, where the HREE are strongly enriched in garnet cores and the concentrations
 711 decreases towards the rims. Despite five spots with a slightly positive Eu anomaly
 712 ($\text{Eu}/\text{Eu}^* = 1.01$ to 1.57), the generally mild negative Eu anomaly ($\text{Eu}/\text{Eu}^* = 0.59$ to

713 0.98) in this sample is interpreted as a response to the presence of plagioclase in the
714 metamorphic assemblage. Garnet from this sample shows Lu enrichment in several
715 growth zones of the crystal (Fig. 12b), whereas another analysed crystal (Fig. S4)
716 shows a bell-shaped profile suggesting Lu partitioning into the core. For this reason,
717 we interpret the Lu–Hf garnet-WR age of 563 ± 12 Ma as representing an average age
718 of the garnet growth in sample MAB56A. Hf mean content acquired in LA–ICP–MS
719 analyses (2 ppm) slightly differ from the value found after garnet isotope dilution (2.5
720 ppm) and may suggest that some ilmenite micro-inclusions were dissolved together
721 with garnet. However, ilmenite is considered part of the stable mineral assemblage,
722 together with garnet. As such, its presence as inclusions in the garnet crystals should
723 not influence the resulting age estimate.

724 The peak PT conditions reached during garnet growth were estimated at ca. 550–
725 570°C and 4.5–5.5 kbar (Fig. 6). We emphasize, however, that preserved garnet grains
726 are often only relict crystals, which we interpret as the result of strong retrogression.
727 Thus, as our PT estimates are based primarily on garnet compositions, this suggests
728 potentially higher peak metamorphic conditions than is indicated by the matrix
729 assemblage. Thus, staurolite crystals might have been present during the
730 metamorphic peak, as suggested by the thermodynamic model (Fig. 6), and it were
731 subsequently consumed during retrogression, while some garnet crystals remained
732 preserved. Therefore, we interpret the Lu–Hf garnet age (563 ± 12 Ma) and the PT
733 conditions estimated from the garnet composition as reflecting the metamorphic peak
734 in this region of the PC prior to the retrograde re-equilibration of sample MAB56A.

735

736 **4.1.4. MAB56A - Retrogression in the northwestern Porongos Complex (ca. 540** 737 **Ma)**

738

739 Monazite in sample MAB56A appears in garnet cracks together with chlorite, and
740 its growth thus appears to be closely related to garnet chloritization (Fig. 13e, f) and
741 overall retrograde overprint of the (unknown) peak mineral assemblage. Monazite
742 grains display a strong variation in HREE content. Colour-coded REE curves and
743 corresponding dates in the U–Pb concordia diagram (Fig 13c, d) show that the variation
744 in HREE content is not reflected in the U–Pb date of the analysed grains, as they all
745 overlap and form a homogeneous cluster in the concordia diagram. Such results
746 suggest that all dated grains represent the same monazite-growing event. The Th/U
747 ratios of the analysed crystals are similar and thus support this interpretation. In this

748 sample, garnet cores are systematically richer in HREE than their rims (Fig. 13a). We
749 thus interpret the variation of monazite HREE content as related to the position of the
750 monazite grain during its growth with respect to the garnet i.e., monazites that grew
751 due to breakdown of the garnet core are richer in HREE, whilst those related to the
752 breakdown of garnet rims have lower HREE.

753 An alternative interpretation by Hagen-Peter et al. (2016) suggests a time-related
754 coupling of garnet breakdown and monazite growth. In such a case, the older monazite
755 grains would be HREE depleted, as they would have grown from garnet rims, whereas
756 the younger monazites related to the dissolution of garnet cores would be richer in
757 HREE. Although this interpretation cannot be fully discarded, the resolution of our
758 dating is not high enough to determine a relationship between age and HREE content.
759 Another alternative proposed by Hacker et al. (2019) suggests that temperature
760 elevation caused by a heating event could raise the partitioning coefficient of HREE
761 into monazite, allowing new grains to support a larger amount of HREE in their
762 structure. The spatially and temporally nearest intrusion is the Capané metagranite,
763 which according to Zvirtes et al. (2017) crystallized at 603 ± 6 Ma (U–Pb zircon age)
764 and has a metamorphic age of 539 ± 9 Ma (U–Pb age from zircon rims and titanite
765 age). Such data indicate that the intrusion is too old to provide heat at ca. 540 Ma. On
766 the other hand, the metamorphic age of the Capané metagranite is in accord with the
767 monazite age of the metasedimentary sample MAB56A.

768 The Eu anomalies in MAB56A monazite and garnet are similar ($\text{Eu}/\text{Eu}^*_{\text{mon}} =$
769 0.36 to 0.63 ; $\text{Eu}/\text{Eu}^*_{\text{grt}} = 0.59$ to 1.56). Also, distribution coefficients between monazite
770 and garnet for some REEs (La–Tb; Fig 14c, d) follow the expected equilibrium values
771 from previous studies (Hermann & Rubatto, 2003; Rubatto et al., 2006), although
772 petrographic observations attest to disequilibrium between these minerals (Fig. 14f).
773 On the other hand, Kd curves for the HREE suggest equilibrium only in a few cases
774 and most of the HREE Kd curves for monazite/garnet core and garnet mantle deviate
775 from expected equilibrium values (Fig. 14c, d). The HREE Kd values for
776 monazite/garnet rim show a large spread (up to three orders of magnitude) for each
777 element, where some of the values match the expected equilibrium values, some are
778 higher, and some are lower (Fig. 14c, d). This reflects the strongly variable HREE
779 content of the monazite itself (Fig. 13b), and as mentioned above, we interpret this
780 feature as a result of the variable availability of HREEs during monazite growth, which
781 will largely depend on the distance of the growing monazite from the dissolving garnet,
782 as well as on the particular part of the garnet (core, mantle, rim) releasing the HREEs.

783 Thus, we interpret the monazite U–Pb SIMS concordia age of 541 ± 7 Ma (2σ)
784 as the time of retrograde overprint of sample MAB56A.

785

786 **4.1.5. BD03 – Prograde metamorphism in the Passo Feio Complex (ca. 570 Ma)**

787

788 The garnet Lu–Hf dating of sample BD03 yielded an age of 571 ± 13 Ma. In
789 agreement with previous works (Bitencourt, 1983; Costa et al., 2021), we interpret the
790 garnet in this sample as syn-kinematic to the main progressive deformational-
791 metamorphic event in the complex, which is represented by the main schistosity.
792 Therefore, the ca. 570 Ma age is interpreted as the mean age of the prograde
793 metamorphism of the Passo Feio Complex. Also, as Lu is not concentrated within one
794 growth zone of the garnet (Fig. 12c), the result of the Lu–Hf garnet–WR dating is
795 considered an average age of the garnet growth in sample BD03. The mean Hf content
796 acquired by LA-ICP-MS (1 ppm) presents a discrepancy when compared to the value
797 found from garnet isotope dilution (4 ppm). However, as in sample MAB51B, all the
798 garnet aliquots stay aligned in the isochron, and thus, the same interpretation is applied
799 to BD03 sample, as well, which indicates the age is likely trustful.

800 Thermodynamic modelling of sample BD03 places the peak metamorphic
801 conditions of this event at 560–580 °C and 4.7–6.4 kbar, with initial garnet growth at
802 525–545 °C and 4.1–4.5 kbar. The data agree with estimates of Costa et al. (2021) for
803 a nearby sample of a garnet-staurolite schist, whereas their additional estimate for a
804 staurolite-free garnet phyllite places the metamorphic peak to 500–510 °C and 5–6.4
805 kbar (Table 4).

806 Published geochronological data for the main metamorphic event in the PFC are
807 rather limited. A single SHRIMP spot in a zircon rim yielded a date of 685 ± 12 Ma
808 (Remus et al., 2000) was associated with the metamorphic peak and thus contrasts
809 with the 571 ± 13 Ma Lu–Hf garnet age. However, the available image (Fig. 5i in Remus
810 et al., 2000) suggests that the microprobe beam size was larger than the zircon rim
811 width, which points to a possible mixed analysis with the Tonian (843 Ma) zircon core.
812 A metamorphic event at ca. 685 Ma cannot be discarded, however if it took place, it
813 must have been erased by the ca. 570 Ma metamorphic event, as the sample used in
814 this paper was collected from the highest metamorphic zone of the complex.

815 A second, low-pressure metamorphic event (M_2) overprinted the peak mineral
816 assemblage in the PFC (Bitencourt, 1983; Costa et al., 2021) and it was interpreted as
817 being related to the emplacement of the Caçapava Granite at 562 ± 8 Ma (SHRIMP

818 U–Pb zircon – Remus et al., 2000). The dextral transcurrent fabric generated in such
819 second event cross-cuts the main metamorphic foliation (Costa et al., 2021). Thus,
820 despite the overlap of the ages within their respective errors (M_1 at 571 ± 13 Ma, and
821 M_2 at 562 ± 8 Ma), metamorphic and structural field relations attest that M_1 have
822 preceded the M_2 event, or they are even progressive phases.

823

825

826 **4.2. Geological significance of the data and an evolutionary scenario of the** 827 **Porongos and Passo Feio complexes**

828

829 The geochronological and metamorphic data presented in this work can be
830 summarized in a P–T–t diagram showing evolution and mutual relationship of the
831 Porongos and Passo Feio complexes (Fig. 15). The data show progressive thickening
832 of the central Dom Feliciano foreland that took place in at least two distinct time
833 periods.

834 The early phase of orogenic evolution in the foreland is recorded by the prograde
835 metamorphism of micaschists in the eastern region of the Porongos Complex.
836 Estimates of metamorphic conditions for the sample MAB51B, and data of De Toni et
837 al. (2021) and Lenz (2006) suggest a clockwise path for this region (see lines 1 and 2
838 in fig. 15). Garnet started to grow at ca. 515–535°C and 3.4–4.4 (MAB51B) and the
839 metamorphic peak was reached at conditions of 560–580°C and 5.8–6.3 kbar
840 (MAB52A – De Toni et al, 2021). Such data demonstrate early thickening of the
841 foreland crust with apparent geothermal gradient of 25 to 35°C/km at ca. 660 Ma, as
842 demonstrated by the Lu–Hf garnet–WR age.

843 The post-exhumation evolution of the eastern Porongos Complex is registered by
844 the destabilization of the peak metamorphic assemblage and growth of andalusite
845 crystals in some of the micaschist samples (De Toni et al., 2021; Lenz, 2006). Lenz
846 (2006) estimated the conditions of this event at 550–560°C and 2.7 kbar. As discussed
847 above, we associate these fluid-triggered mineralogical changes with the growth of
848 monazite in sample MAB51B dated at ca. 615 Ma. All these data suggest that the
849 eastern PC was exhumed between ca. 660 and 615 Ma, before the onset of extensive
850 magmatic activity in the region.

851 The second phase of thickening of the foreland is recorded in the northwestern
852 region of the Porongos Complex (lines 3 and 4 in fig. 15) and in the Passo Feio

853 complexes (lines 5, 6 and 7 in fig. 15). The evolution of sample MAB56A from the
854 northwestern Porongos Complex shows the onset of garnet growth at 520–540°C and
855 3.9–5.3 kbar and the metamorphic peak at ca. 550–570°C, and 4.5–5.5 kbar. Together
856 with Lu–Hf garnet–WR dating, such data indicate a burial event at ca. 565 Ma. The
857 exhumation of the northwest region of the PC was associated with severe chloritization
858 of the garnet-bearing peak mineral assemblage. It took place at around 540 Ma, as
859 suggested by monazite growth at the expense of the ca. 565 Ma garnet. Chlorite
860 geothermometers (Cathelineau & Nieva, 1985; Cathelineau, 1988; De Caritat et al.,
861 1993; Vidal et al., 2001) suggest temperatures of 310–440°C during the retrograde
862 overprint, yet the pressure could not be established.

863 Burial of the Passo Feio Complex took place at ca. 570 Ma, as determined by
864 Lu–Hf dating of garnet growth during the main regional metamorphism of the complex.
865 Sample BD03 registers the metamorphic peak of this event at ca. 560–580°C, and 4.7–
866 6.4 kbar. The exhumation of the complex occurred before ca. 560 Ma, which is the age
867 of the Caçapava granite intrusion triggering contact metamorphism at depths shallower
868 than 14 km, as indicated by the crystallization of andalusite (Costa et al., 2021). The
869 exact exhumation path is unclear (line 7 in fig. 15), and either corresponds to a near
870 isothermal decompression path or to exhumation and cooling path followed by re-
871 heating (Costa et al., 2021), both due to the heat input caused by the Caçapava granite
872 intrusion. PT modelling also indicates that andalusite is only stable at temperatures
873 similar to those of the metamorphic peak but at lower pressures (Fig. 9).

874

875

876 Figure 15. P–T–t evolution of the Porongos and Passo Feio complexes, based on the data of
 877 this paper and literature. Depth calculated using average crustal density of 2.8 g/cm³.

878

879 4.3. Tectonostratigraphic subdivision of the Porongos Complex

880

881 Our geochronological and metamorphic data indicate a diachronous
 882 metamorphic evolution of the eastern and northwestern regions of the Porongos
 883 Complex. Such results explain the difference between these two regions, mainly
 884 noticed in the zircon provenance patterns of metasedimentary rocks (Gruber et al.,
 885 2011b, 2016b; Pertille et al., 2015b, 2015a, 2017; Höfig et al., 2018) and protolith ages
 886 of metaigneous rocks (Saalman et al., 2011; Pertille et al., 2017; Höfig et al., 2018;
 887 Battisti et al., submitted).

888 For many authors (e.g. Saalman et al., 2006; Höfig et al., 2018; Battisti et al.,
 889 2018; De Toni et al., 2021), the main metamorphic–deformational event in the PC is
 890 related to the well-known collision in the DFB at ca. 650 Ma (Chemale et al., 2011;

891 Martil, 2016), which generated *W*-verging thrusting of hinterland nappes on top of the
892 foreland (Battisti et al., 2018; De Toni et al., 2021). Our Lu–Hf garnet–WR dating
893 confirms the timing of the main fabric development and metamorphic peak in the
894 eastern region of PC during this ca. 660–650 Ma event. Such data demonstrate that
895 the igneous activity, and the late sedimentation in the northwestern PC are younger
896 than the metamorphic peak recorded in the eastern portion of the PC (Table 5).

897 Battisti et. al. (2018) suggested a second metamorphic–deformational event in
898 the PC, but its absolute timing was unknown. Our Lu–Hf garnet–WR isochron and U–
899 Pb SIMS monazite ages from sample MAB56A indicate that the second event took
900 place from ca. 560–540 Ma and is exclusively recorded west of the Santana da Boa
901 Vista thrust fault. These data indicate that the two basins proposed by Höfig et al.
902 (2018) have had different geological evolution in space and time. The Santana da Boa
903 Vista fault, the main *W*-verging thrust fault of the Porongos Complex (Jost & Bitencourt,
904 1980), represents the best possible limit between these two diachronous basins,
905 referred to as the Cerro da Árvore and Capané sequences in Table 5. To the east of
906 the Santana da Boa Vista fault (eastern Porongos region), the detrital zircon age
907 patterns in metasedimentary rocks suggest pre-collisional deposition of the Cerro da
908 Árvore sequence. On the other hand, to the west of the fault (western Porongos region)
909 the rocks of the pre-orogenic PC basin are interleaved with metamorphosed syn-
910 orogenic sedimentary rocks of the Capané sequence, as first suggested by Höfig et al.
911 (2018).

912

913 **INSERT TABLE 5**

914

915 **4.4. Evolutionary model**

916

917 The Cerro da Árvore sequence of the Porongos Complex, and metasedimentary
918 rocks of the Várzea do Capivarita Complex have been deposited from before ca. 810
919 Ma, as indicated by the age of the associated volcanic rocks (Saalman et al., 2011;
920 Pertille et al., 2017; Battisti et al., submitted), until < ca. 660–650 Ma, when the early
921 orogenic deformation and metamorphism took place (Fig. 16a). The ca. 660–620 Ma
922 collisional event affected the easternmost part of the Cerro da Árvore sequence, which
923 was thrust under the developing hinterland represented by the *W*-verging nappes of
924 the Várzea do Capivarita Complex (Martil et al., 2017; Battisti et al., 2018; De Toni et
925 al., 2021), but had minor effect on the westernmost part of this sequence (Fig. 16b).

926 Sometime between ca. 660 Ma and ca. 615 Ma, the eastern PC was exhumed. The
927 exhumation preceded an extensive magmatic activity in the region, during which at
928 least some intrusions likely exploited the existing nappe boundaries.

929 In the western region, the basin with the pre-orogenic infill of the Cerro da Árvore
930 sequence was probably only mildly affected by the early (660–615 Ma) orogenic
931 phase. On the other hand, after a certain time the basin started receiving syn-orogenic
932 (flysch) sediments of the present-day Capané sequence, now interleaved with the
933 Cerro da Árvore sequence rocks. The flysch sedimentation occurred from ca. 660 Ma
934 to < ca. 570–560 Ma (Fig 16b). At ca. 570–560 Ma, the second episode of crustal
935 thickening occurred. It thrust the eastern region of PC on top of its western region,
936 which caused metamorphism and deformation of both the Capané and Cerro da Árvore
937 (at the bottom) sequences (Fig 16c). The MAB56A locality represents the region where
938 the Cerro da Árvore and Capané sequences are interleaved. The destabilization of
939 garnet and appearance of monazite in equilibrium with retrograde chlorite at ca. 540
940 Ma likely indicates the exhumation-related decrease of metamorphic temperatures
941 from ca. 560 Ma to ca. 540 Ma.

942 We speculate that the Passo Feio Complex further to the west of the Porongos
943 Complex represents an originally independent basin, which seems to register only the
944 younger metamorphic and deformation event at ca. 570 Ma (Fig. 16b,c). Our new data
945 suggest that the crustal thickening and overall tectonic activity in the central Dom
946 Feliciano Belt foreland at this time was much more extensive than so far published.
947 Such data indicate that the Passo Feio and western Porongos complexes record an
948 orogenic front migration towards the west as a part of a long-lived transpressive
949 deformation in the Dom Feliciano Belt, which has started at ca. 660–650 Ma (see also
950 De Toni et al., 2021 or Percival et al., 2022).

951

952

953 Figure 16 – Model of pre-orogenic setting and orogenic evolution of the Central Dom Feliciano
 954 Belt foreland (Porongos and Passo Feio complexes) and hinterland (Várzea do Capivarita
 955 Complex).

956

957 5. Conclusions

958

959 Petrochronological study utilizing petrological modelling combined with Lu–Hf
 960 garnet–WR ages, U–Pb monazite SIMS ages and Y–REE data in garnet and monazite
 961 was performed in metasedimentary rocks of the central Dom Feliciano Belt foreland.
 962 The results allow us to draw the following conclusions:

963 1) Metasedimentary rocks of the eastern Porongos Complex display a main
 964 metamorphic event at 662 ± 13 Ma (Lu–Hf isochron garnet–whole-rock age). Such

965 event took place at ca. 515–535°C and 3.4–4.4 kbar and reached metamorphic peak
966 at ca. 560–580 °C, 5.8–6.3 kbar. This episode represents an early orogenic thickening
967 event in the foreland as a response to the beginning of transpressive convergent
968 evolution of the Dom Feliciano Belt.

969 2) The monazite age of 614 ± 6 Ma (U–Pb SIMS) suggests that the eastern
970 Porongos Complex was exhumed sometime between ca. 660 and 615 Ma. The growth
971 of monazite, andalusite and secondary white mica was likely triggered by a release of
972 fluids during crystallization of neighboring syenitic rocks of similar age.

973 3) Syn-orogenic sediments (Capané sequence) were deposited in the
974 western part of the Porongos Complex at unspecified time between ca. 660 to ca. 560
975 Ma. The main metamorphic and deformational event in this region took place at
976 conditions of ca. 550–570°C and 4.5–5.5 kbar at 563 ± 12 Ma (garnet–WR Lu–Hf
977 isochron age).

978 4) The exhumation of the western PC is dated by the appearance of
979 monazite crystalizing during garnet breakdown, suggesting retrograde metamorphism
980 at 541 ± 7 Ma (U–Pb SIMS).

981 5) The main metamorphic fabric in the Passo Feio Complex was developed
982 at 571 ± 13 Ma (garnet–WR Lu–Hf isochron age) at metamorphic conditions of 560–
983 580°C and 4.7–6.4 kbar.

984 6) The Western part of the Porongos Complex and the Passo Feio Complex
985 were deformed at ca. 570–565 Ma at similar PT conditions and geothermal gradients.
986 These regions record a second crustal thickening event in the Dom Feliciano Belt and
987 the orogenic front migration towards the west in a long-lived transpressive orogenic
988 system.

1399 Appendix

1400

1401 1. Lu–Hf isotope analysis

1402

1403 The Lu–Hf analyses were carried out at the Geological Institute of the Czech
1404 Academy of Sciences (chemistry) and Faculty of Science, Charles University (MC–
1405 ICP–MS). Garnet concentrate and whole-rock powder were weighted and mixed with
1406 the ^{176}Lu – ^{180}Hf tracer solution. The samples were digested in closed 30ml Savillex
1407 teflon vials using combined acid attack (HF–HNO₃–HCl). First, 0.5 ml HNO₃ + 2 ml HF
1408 (concentrated acids) was added to each sample and left to stand cold in closed vial for
1409 3 hours. Subsequently the bombs were opened and warmed on the hotplate to 90 °C
1410 to evaporate Si and all acids. During this step the major minerals are attacked by the
1411 acids, most of the Si evaporates with the excess HF and the acids used in the following
1412 step thus have the opportunity to attack any resistant minerals without being depleted
1413 by reaction with major silicate phases. After complete evaporation, the mixture of 1.5
1414 ml HNO₃ + 4.5 ml HF was added to the samples, left on a hotplate for two days at 160
1415 °C, and then evaporated to dryness. After that, the samples were treated three times
1416 with 2 ml of concentrated HNO₃ and evaporated to dryness. Next, 1 ml of 6 M HCl was
1417 added and immediately dried down. Finally, 8 ml of 6 M HCl was added and left on a
1418 hotplate at 160 °C in a sealed beaker for 24 hours. The sample was then evaporated
1419 to dryness and 2 ml of 1 M HCl was added for subsequent column chemistry.

1420 The ion exchange column chemistry follows closely that of Anczkiewicz et al.
1421 (2004), which is a down-scale modification of the original setup of Patchett and
1422 Tatsumoto (1980). The separation of Hf (+ Ti) and Lu (+ Yb and LREE) fractions is first
1423 carried out on a standard cation exchange column using AG50W–X8 resin (200–400
1424 mesh size) and 1 M HCl–0.06 M HF (HFSE elution) and 2.5 M HCl (REE elution). The
1425 final purification of Hf from other HFSE and potentially interfering Lu and Yb takes
1426 place on a second column with Eichrom LN resin (50–100 µm) using technique based
1427 on Lee (1999) employing the mixture of 2 M HCl–0.1 M. The same column is then used
1428 for purification of Lu from other REEs and reduction of Yb in the Lu cut using 4M HCl.

1429 All measurements of Lu and Hf fractions were carried out using a THERMO
1430 Neptune multi-collector (MC) ICP–MS in the labs of the Faculty of Science, Charles
1431 University in Prague. Hafnium isotopic compositions were analysed in a static mode
1432 using Faraday cups with the following configuration: L4 – ^{172}Yb , L3 – ^{174}Yb , L2 – ^{175}Lu ,
1433 L1 – ^{176}Hf , C – ^{177}Hf , H1 – ^{178}Hf , H2 – ^{179}Hf , H3 – ^{180}Hf , H4 – ^{182}W . Samples were

1434 aspirated to the instrument in 0.5 M HNO₃–0.25 M HF mixture using CETAC Aridus II
1435 desolvating nebulizer. The data acquisition procedure consisted of 40 integration
1436 cycles acquired over a period of ca. 6 min, followed by ca 5 min of washout with a
1437 mixture of 1.2 M HNO₃–0.5 M HF composition. The raw data were processed off-line
1438 using on-purpose-built calculation EXCEL spreadsheet. Repeated measurements of
1439 50 ppb JMC–475 standard over the period of analyses yield $^{176}\text{Hf}/^{177}\text{Hf} = 0.282158 \pm 7$
1440 (2SE, n=7), which is in agreement within the error with the reference data (Chu et al.,
1441 2002). The spike stripping routine employing the ratio of $^{179}\text{Hf}/^{177}\text{Hf}$ iteratively
1442 deconvoluting to the natural value of 0.7325 (Patchett & Tatsumoto, 1980) and
1443 exponential mass-bias correction were used to obtain Hf isotopic composition and Hf
1444 concentration of the spiked samples.

1445 For Lu isotopic analyses, Faraday cup configuration was as follows: L3 – ^{171}Yb ,
1446 L2 – ^{172}Yb , L1 – ^{173}Yb , C – ^{174}Yb , H1 – ^{175}Lu , H2 – ^{176}Lu , H3 – ^{177}Hf . The sample
1447 aspiration was identical to the Hf measurements with the difference that HF-free acids
1448 were used for sample introduction (0.5 M HNO₃) and washout (1.5 M HNO₃). The data
1449 acquisition procedure consisted of 40 integration cycles acquired over a period of ca.
1450 3 minutes, followed by 4 min of washout. The raw data were processed off-line using
1451 on-purpose-built calculation EXCEL spreadsheet. Repeated measurements of natural
1452 Lu and Yb standard solutions were carried out to check the accuracy of the isotopic
1453 ratios measurements. The mass-bias correction (exponential law) of the spiked
1454 $^{176}\text{Lu}/^{175}\text{Lu}$ ratio was done using the natural Yb present in the sample (reduced in the
1455 3rd step of column chromatography to be ca. 1/10 of the amount of Lu to be suitable
1456 for mass bias correction while not causing excessive interference on ^{176}Lu mass) and
1457 the true ratio of $^{174}\text{Yb}/^{172}\text{Yb} = 1.45198$ (Thirlwall & Anczkiewicz, 2004). The value of
1458 $^{176}\text{Lu}/^{175}\text{Lu}$ was then used to calculate the concentration of Lu in the samples. The
1459 accuracy of the method was checked by measurement of spiked aliquot of BCR–2
1460 reference material, which gave $^{176}\text{Hf}/^{177}\text{Hf} = 0.282859 \pm 11$, Hf = 5.00 ppm and Lu =
1461 0.514 ppm, which are in good agreement with published values of 0.282866 ± 11
1462 (Jweda et al., 2016), 4.8 ± 0.2 and 0.51 ± 0.02 (U.S. Geological Survey Certificate of
1463 Analysis, online source) respectively.

1464 2. U–Pb monazite dating methodology

1465

1466 The samples were processed through a rock crusher and a hammer mill.
1467 Monazite and garnet were separated using a Wilfley table, a Frantz™ isodynamic
1468 magnetic separator and heavy liquids in the laboratories of the Department of
1469 Geosciences at the UiT The Arctic University of Norway in Tromsø. Subsequently,
1470 monazite grains were handpicked under a binocular microscope and selected grains
1471 were mounted in one-inch epoxy disks. In order to identify internal microstructures and
1472 possible compositional zoning, backscattered electron (BSE) images of monazite
1473 grains were made by Zeiss Merlin Scanning Electron Microscope (SEM) housed at the
1474 Faculty of Health Sciences of the same university.

1475 Monazite U–Th–Pb analyses by SIMS were performed on a Cameca IMS 1280
1476 ion probe at NordSIM at the Swedish Museum of Natural History in Stockholm.
1477 Operating parameters with regard to primary beam and mass resolution were similar
1478 to those used for zircon, broadly following the protocols described in (Gasser et al.,
1479 2015). The principal difference from zircon is that the monazite analyses employed
1480 both a smaller entrance slit (30 µm instead of 75 µm) to limit the secondary beam
1481 intensity, as well as a smaller energy slit (30 eV instead of 45 eV) together with a -30
1482 eV energy offset (applied via sample high voltage) on all the Pb, ThO_x and UO_x (where
1483 x = 0, 1 or 2) peaks of interest in order to minimize matrix differences in potentially
1484 chemically diverse monazite, and eliminate a small ThNdO₂²⁺ interference on ²⁰⁴Pb
1485 identified in earlier monazite studies (e.g. Kirkland et al., 2009). Secondary beam
1486 centring and optimization steps were performed as for zircon, but using the CePO₂⁺
1487 matrix peak at nominal mass 203. U–Pb ratios were calibrated against a 425 Ma
1488 reference monazite from a metapelite of the Wilmington Complex, Delaware (sample
1489 44069, Aleinikoff et al., 2006), using a two-dimensional power law calibration
1490 approach, i.e. $(\text{Pb}/\text{U})_{\text{true}} = f.(\text{Pb}/\text{U})_{\text{meas}}, \text{UO}_2/\text{U}_{\text{meas}}$ based on measurement of these
1491 ratios in the reference monazite.

492 Table 1. Representative microprobe analyses of minerals (The analyses were recalculated based on the following nr. of oxygen atoms:
 493 PI = 8O; Bt, Ms = 11O; Grt = 12O; Chl = 14O; St=24O). All analyses are available as supplementary data.

Dear Mr. Battisti,

Your submission entitled "Unravelling major magmatic episodes from metamorphic sequences of the Dom Feliciano Belt central sector, Brazil – a comparative study of geochronology, elemental geochemistry, and Sr-Nd data" (Regular Article) has been received by Lithos.

Please note that submission of an article is understood to imply that the article is original and is not being considered for publication elsewhere. Submission also implies that all authors have approved the paper for release and are in agreement with its content.

You will be able to check on the progress of your paper by logging on to <https://www.editorialmanager.com/lithos/> as Author.

Your manuscript will be given a reference number in due course.

Thank you for submitting your work to this journal.

Kind regards,

Journal management

ABSTRACT

The geochemical and isotopic signatures of magmatic events preserved in deformed metasedimentary sequences may inform about the basin's geological setting and reconstruct its original stratigraphy. This paper discusses geochemical and Sr-Nd isotopic data available in the literature for the metavolcanic rocks interleaved with highly-deformed metasedimentary rocks in three metamorphic complexes from the Dom Feliciano Belt, central sector, southernmost Brazil: the high-grade Várzea do Capivarita, and the lower greenschist to amphibolite facies Porongos and Passo Feio complexes. We also provide new elemental and isotopic geochemical data for seven metavolcanic samples collected from the Passo Feio and Porongos complexes along with U-Pb LA-ICPMS zircon determinations for selected metavolcanic rocks. The dataset was initially sorted into three groups based on REE patterns: i) Group 1 - LREE enrichment over HREE ($\text{LaN/YbN} \approx 10$) with negative Eu anomalies ($\text{Eu/Eu}^* = 0.38$ to 0.86); ii) Group 2 - enhanced LREE enrichment ($\text{LaN/YbN} = 12$ to 44) and no Eu anomaly ($\text{Eu/Eu}^* = 0.94$ to 1.07), and iii) Group 3 - negative Eu anomaly ($\text{Eu/Eu}^* \approx 0.70$), but higher LREEs absolute values ($\text{LaN/YbN} \approx 22$). A basic metavolcaniclastic sample, referred to as *Bmvc*, displays a fourth pattern, as trace element data show that it does not belong to any of the three established groups. New U-Pb LA-ICPMS zircon analyses of two acidic metavolcanic rocks from the Passo Feio Complex yielded crystallisation age of the protolith at 580 ± 2 Ma (2σ). Magmatism in the three studied complexes can be grouped into two diachronous magmatic events. Group 1 samples account for a first magmatic event at 810–780 Ma in the Várzea do Capivarita and Porongos (Cerro da Árvore sequence) complexes. They represent a magmatic association produced from subduction-related sources, with significant contribution of crustal materials, according to geochemical arguments expressed as $^{87}\text{Sr}/^{86}\text{Sr}_{(790 \text{ Ma})} > 0.715$ and $\epsilon\text{Nd}_{(790 \text{ Ma})}$ from -5 and -11 (up to -22). Groups 2 and 3 and *Bmvc* account for the second magmatic event at ca. 600 to 580 Ma as recorded in the Passo Feio and western Porongos (Capané sequence) complexes. Groups 2 and 3 rocks are interpreted to have been sourced from a subduction-related enriched mantle, but without major crustal contamination, as in a back-arc geological setting, as expressed by $^{87}\text{Sr}/^{86}\text{Sr}_{(580 \text{ Ma})} = 0.7035\text{--}0.7050$ and $\epsilon\text{Nd}_{(580 \text{ Ma})} > -10$. For *Bmvc*, the data suggest a mantle-derived origin without a significant contribution of subduction-related sources, possibly indicating multiple sources for this newly-described and not yet fully reconstructed Ediacaran magmatism. Our comparative study leads to the novel

conclusion of a shared tectonic evolution between the Passo Feio Complex and the eastern Porongos Complex (Capané sequence) at ca. 600–580 Ma. Our data also corroborate a shared tectonic evolution between the western Porongos Complex (Cerro da Árvore sequence) and the Várzea do Capivarita Complex at ca. 810–770 Ma, as reported by previous authors.

Keywords: *Metavolcanic rocks, Magmatic events, Sr-Nd isotopes, U-Pb zircon dating, Dom Feliciano Belt, Reconstruction of ancient geological settings*

1 **1. INTRODUCTION**

2
3 Magmatic events in sedimentary sequences, represented either as sills, dykes or
4 volcaniclastic successions, can provide elucidative information about the timing during
5 the deposition (e.g. Vidal and Alric, 1994; Tull et al., 2014). Moreover, elemental and
6 isotopic signatures of such magmatic members can provide first-order information
7 about the geological setting of the studied basin (DePaolo and Wasserburg, 1979;
8 Pearce et al., 1984). When deformed within the metasedimentary package, meta-
9 igneous rocks may also help construct the minimum timing of
10 deformation/metamorphism of the sequence (e.g. Martil et al., 2017; Percival et al.,
11 2021). Therefore, interbedded metavolcanic and metasedimentary successions
12 present in strongly deformed belts can be used to reconstruct the original stratigraphic
13 record that was commonly modified due to deformation and metamorphism (e.g. Vidal
14 and Alric, 1994; Tull et al., 2014; Martil et al., 2017; Percival et al., 2021).

15 In southeastern South America, the Dom Feliciano Belt is a long-lived
16 Neoproterozoic belt with counterparts in the Kaoko and Gariep belts on the African
17 side. Its original stratigraphic relations are strongly overprinted by later deformation.
18 Reconstructing the original stratigraphy of its deformed basins is difficult, as it is for
19 most of the ancient belts in the world. Consequently, the DFB medium to high-grade
20 metamorphic units discussed in this paper have been treated as unrelated for several
21 decades.

22 However, the recognition of volcanic rocks common to some highly contrasting
23 final products as granulites and greenschists or similar rock types in different structural
24 settings led Martil et al. (2017) to admit that such sequences might have been part of
25 a single basin. Structural studies carried out by Battisti et al. (2018) explored this
26 possibility further and first attempted to reconstruct the paleoenvironment by using also
27 the geochronological data reported by several authors (e.g. Saalman et al., 2011;
28 Martil, 2016; Martil et al., 2017; Pertille et al., 2017) by which it became clear that both
29 volcanic protoliths were ca. 790 Ma old and closely related in composition. The
30 synchronicity of the magmatism and sedimentation between these high- and low-grade
31 metamorphic complexes was explored by several authors (e.g. Battisti et al., 2018; De
32 Toni et al., 2020b) for structural correlation. An elemental and isotope geochemistry
33 approach of these high- and low-grade sequences (Martil et al., 2017) hints further at
34 their correlation but does not present enough data to be statistically representative.

35 On the other hand, provenance studies of greenschist-facies supracrustal rocks
36 carried out by Pertille et al. (2015, 2017) and Höfig et al. (2018) reported the presence
37 of much younger zircons in parts of this supracrustal sequence, which put previous
38 results in check and would call for structural data to explain. The scarcity of integrative
39 approaches has thus hindered further correlations of these metamorphic sequences
40 that would consider aspects such as structural geology, elemental and isotope
41 geochemistry, petrology and geochronology.

42 This paper discusses geochemical and Sr-Nd isotopic data available in the
43 literature for the metavolcanic interleaved with metasedimentary rocks of three
44 metamorphic complexes from the Dom Feliciano Belt: the high-grade Várzea do
45 Capivarita Complex (i), and the lower greenschist to amphibolite facies Porongos (ii)
46 and Passo Feio (iii) complexes. We also present new major/trace element and Sr-Nd
47 isotope data for seven metavolcanic samples collected from the Passo Feio and
48 Porongos complexes along with U–Pb LA-ICPMS zircon determinations for selected
49 metavolcanic rocks. The integration of pre-existing and newly-obtained data allows us
50 to go further into the discussion of possible correlations among these metamorphic
51 sequences and their implications for the reconstruction of pre-orogenic environments
52 and the evolution of the DFB central sector.

53

54 **2. GEOLOGICAL SETTING**

55

56 **2.1 Dom Feliciano-Kaoko-Gariép orogenic system**

57

58 The study area is located in the central sector of the Dom Feliciano Belt (DFB –
59 Fig. 1), which is the South American part of an N–S trending Neoproterozoic orogenic
60 system that also involves the Kaoko and Gariép belts along the Atlantic coast of
61 southern Africa. The main tectonic fabric of the whole orogenic system was developed
62 during the amalgamation of the Gondwana supercontinent (e.g. Rapela et al., 2011;
63 Ramos et al., 2017; Oriolo et al., 2017).

64 The Dom Feliciano Belt (DFB) was formed during the Brasiliano/Pan-African
65 Orogenic Cycle, which started at ca. 840–770 Ma by igneous activity and associated
66 sedimentation interpreted by some authors as related to a continental arc (Koester et
67 al., 2016; Martil et al., 2017; Battisti et al., 2018; De Toni et al., 2020b) or as generated
68 in a back-arc/rift setting (Konopásek et al., 2018; Will et al., 2019). The main
69 contractional tectonic regime started at ca. 660–650 Ma (e.g. Gross et al., 2006, 2009;

70 Oyhantçabal et al., 2009; Lenz et al., 2011; Martil, 2016; Peel et al., 2018; Will et al.,
71 2019; De Toni et al., 2020a; Percival et al., 2021, 2022). However, the contraction
72 continued until at least 580–550 Ma, as recorded by ongoing crustal thickening and
73 associated metamorphism on both sides of the orogenic system (Frimmel and Frank,
74 1998; Goscombe and Gray, 2008; Höfig et al., 2018; Percival et al., 2022).

75 The DFB central sector outcrops in southernmost Brazil (Rio Grande do Sul state)
76 and is usually divided into Western, Central and Eastern domains (Fragoso-Cesar et
77 al., 1986; Fernandes et al., 1992; Basei et al., 2000) (Fig. 1). The Western and Central
78 domains represent the orogenic foreland, which is now extensively covered by late-
79 orogenic volcano-sedimentary deposits (Oliveira et al., 2014; Paim et al., 2014). The
80 Western Domain consists of Paleoproterozoic rocks (~2.5 to 2.0 Ga - Hartmann et al.,
81 2000), ophiolite remnants (~920-890 Ma - Arena et al., 2016) and juvenile, arc-related
82 rocks of the São Gabriel Block (~750-690 Ma - Lena et al., 2014) with associated
83 metasedimentary complexes. The Central Domain is represented mainly by the
84 Porongos Complex (PC), composed of volcano-sedimentary rocks (Jost and
85 Bitencourt, 1980; Saalman et al., 2006; Pertille et al., 2017) of Tonian to Ediacaran
86 age (Saalman et al., 2011; Pertille et al., 2017; Höfig et al., 2018) with locally exposed
87 Paleoproterozoic basement (~2.26-2.0 Ga - Hartmann et al., 2003; Philipp et al., 2008).

88 The Eastern Domain represents the hinterland of the Dom Feliciano Belt, and it
89 features mostly post-collisional granitic rocks (Bitencourt and Nardi, 1993, 2000;
90 Philipp and Machado, 2002). In southernmost Brazil, such Neoproterozoic (~650 and
91 580 Ma) granitic rocks contain roof pendants and crustal xenoliths with at least three
92 distinct ages: (i) Paleoproterozoic (2.2 and 2.0 Ga – Leite et al., 2000; Gregory et al.,
93 2015), (ii) Mesoproterozoic (ca 1.5 Ga – Chemale et al., 2011) and (iii) Tonian (ca. 770
94 - 800 Ma - Koester et al., 2016; Martil et al., 2017, 2011). The most extensive
95 occurrence of the ca. 770 - 800 Ma rocks is the high-grade Várzea do Capivarita
96 Complex (VCC) (Fig. 1, 2).

97

98

99 Figure 1. A) Overview geological map and main tectonic domains of the Dom Feliciano–
 100 Kaoko–Gariép orogenic system (modified after Bitencourt and Nardi, 2000 and Konopásek et
 101 al., 2018). Relative Position of Africa and South America is shown at 140 Ma - after Heine et
 102 al., 2013. Dom Feliciano Belt domains in the Rio Grande do Sul state are shown in the inset.
 103 Location of figure 2 is indicated. Cities: FL – Florianópolis, PA – Porto Alegre, MV –
 104 Montevideo.

2.2 *Várzea do Capivarita Complex*

The Várzea do Capivarita Complex (VCC - Martil et al., 2011, 2017) is situated in the DFB hinterland. It comprises part of the basement intruded by Late Neoproterozoic granites in southernmost Brazil (Fig. 1). It is interpreted as a W-verging nappe thrust onto the Central Domain (Battisti et al., 2018; De Toni et al., 2021). These well-preserved roof pendants (Martil et al., 2017 - Fig. 2) comprise tectonically interleaved granulite facies orthogneisses and paragneisses (Martil et al., 2011, 2017). According to these authors, the orthogneisses are mostly tonalitic and related to a Tonian mature magmatic arc (~790-780 Ma – U–Pb zircon). Paragneisses comprise metapelites and calc-silicate rocks (Martil et al., 2011).

Two main deformation phases are described in the VCC and are related to one single tectono-metamorphic event under granulite facies conditions (Gross et al., 2006; Martil, 2016). The VCC gneisses were tectonically interleaved along a sub-horizontal banding, with top-to-the-west shear sense (Martil et al., 2011; Martil, 2016). Dextral strike-slip to slightly oblique vertical NNE-SSW shear zones progressively overprint the thrusting structures, which are locally preserved (Martil, 2016). The granulite-facies conditions achieved ca. 750 - 800 °C and 3-5 kbar in the VCC metapelites (Gross et al., 2006; Costa et al., 2020; De Toni et al., 2021) at 650 – 640 Ma (Martil, 2016).

2.3 *Porongos Complex*

The Porongos Complex (PC) is part of the Dom Feliciano Belt foreland and comprises Neoproterozoic supracrustal rocks metamorphosed at lower greenschist to middle amphibolite facies (Jost and Bitencourt, 1980; Saalman et al., 2006; Pertille et al., 2017; Höfig et al., 2018; De Toni et al., 2021). The PC comprises metasedimentary and metavolcanic rocks, some ultramafic lenses, and less often, deformed granitoids (Jost and Bitencourt, 1980; Marques et al., 2003; Zvirtes et al., 2017). Some authors interpret the ultramafic lenses as ophiolite remnants (e.g. Arena et al., 2018; Werle et al., 2020).

The PC is divided into two tectonic-stratigraphic sequences – Cerro da Árvore and Capané, of different geological evolution (Battisti, 2022). Apart from their contrasting metamorphic evolution, the Cerro da Árvore and Capané sequences also display variable ages of their associated intermediate to acidic metavolcanic rocks (Saalman et al., 2011; Zvirtes et al., 2017; Pertille et al., 2017; Höfig et al., 2018).

140 Cerro da Árvore is the oldest sequence, and its pre-collisional sedimentation is
 141 associated with ca. 810-780 Ma metavolcanic rocks, while the Capané sequence was
 142 deposited in a syn- to late-collisional scenario and is interleaved with ca. 600 Ma
 143 metavolcanic rocks (Battisti, 2022).

144

145

146

147 Figure 2. Geological map of the studied area with the sampled sites indicated. DCZS – Dorsal
 148 do Canguçu Shear Zone; PCSZ – Passo das Canas Shear Zone. Regions of Porongos
 149 Complex are shown inset. – References: 1- (Paim et al., 2014); 2-(Padilha et al., 2019); 3-(Rivera,
 150 2016; Padilha et al., 2019); 4-(Bitencourt et al., 2015; Knijnik, 2018; Vieira et al., 2020); 5-(Knijnik, 2018;
 151 Vieira et al., 2020); 6-(Remus et al., 2000); 7-Battisti et al submitted b; 8-(Philipp et al., 2016b); 9-(Höfig
 152 et al., 2018); 10-(Saalmann et al., 2011; Pertille et al., 2017); 11-(Martil et al., 2017); 12-(Gross et al.,
 153 2006; Chemale et al., 2011; Philipp et al., 2016a; Martil et al., 2017); 13-(Chemale et al., 2011); 14-
 154 (Leite et al., 2000; Hartmann et al., 2003; Saalmann et al., 2011; Gregory et al., 2015).

155

156 The Porongos Complex is divided into Eastern and Western regions separated
 157 by the main W-verging structure called Santana da Boa Vista thrust fault (Jost and
 158 Bitencourt, 1980 - Fig. 2). Rocks of the Cerro da Árvore sequence are widespread over
 159 the Eastern and Western Porongos regions, whilst the Capané sequence rocks are
 160 only present in the Western region. The peak PT conditions of the PC Eastern region
 161 were estimated at 560–580 °C, and 5.8–6.3 kbar (Lenz, 2006; De Toni et al., 2021)

162 and the metamorphic age was established at 662 ± 13 Ma (Lu-Hf garnet–whole-rock –
163 Battisti, 2022). In contrast, the metamorphic peak in the Western region occurred at
164 $550 - 570^\circ\text{C}$ and $4.5 - 5.5$ kbar at 563 ± 12 Ma (Lu-Hf garnet-whole-rock – Battisti,
165 2022). Such metamorphic ages are associated with two different periods of crustal
166 thickening in the Dom Feliciano Belt.

167

168 **2.4 Passo Feio Complex**

169

170 The Passo Feio Complex is part of the so-called São Gabriel Block, sited in the
171 Western Domain, that contains the largest volume of juvenile magmatic rocks in the
172 DFB (e.g. Saalman et al., 2005, 2007; Lena et al., 2014; Arena et al., 2016, 2017).
173 According to Arena et al. (2016), some igneous rocks of this block may have been part
174 of an oceanic domain (ophiolites at 920–890 Ma), accreted to a juvenile arc (ca. 880
175 Ma Passinho event of Leite et al., 1998) that evolved towards a continental magmatic
176 arc (770–690 Ma; Lena et al., 2014). The ocean closure was interpreted to have
177 occurred at 690–650 Ma (Lena et al., 2014) or 650–600 Ma (Arena et al., 2017),
178 whereas late granitic magmatism took place at ca. 585 Ma (Arena et al., 2017). Arc-
179 related metaigneous rocks of the São Gabriel Block are surrounded by supracrustal
180 metamorphic rocks.

181 The Passo Feio Complex is traditionally considered to be located at the eastern
182 border of the São Gabriel Block (Fig. 1, 2), separated from the easterly Porongos
183 Complex by a geophysical anomaly (Costa, 1997). However, the meaning of such
184 anomaly is unclear because it is covered by post-orogenic sediments of the Camaquã
185 Basin (Fig. 2). Furthermore, some authors interpreted this anomaly as a suture
186 (Fernandes et al., 1995; Costa, 1997), whereas others (e.g. Costa et al., 2021) interpret
187 it to represent a dextral transcurrent shear zone. As no further arguments confirm this
188 magnetic anomaly as a suture, the relation between the Passo Feio Complex (in the
189 Western Domain) and the units to the east (Central and Eastern domains) remains
190 uncertain.

191 The PFC (Fig. 2) comprises phyllites, metapelitic schists, amphibole-bearing
192 rocks such as amphibolites, metagabbros and amphibole schists, acidic to
193 intermediate metavolcaniclastic rocks, magnesian schists and marble lenses
194 (Bitencourt, 1983; Bitencourt and Hartmann, 1984a, 1984b; Costa et al., 2021). The
195 age of the associated meta-igneous rocks is unknown. The PFC is part of an antiformal
196 structure of sub-horizontal axis plunging either NNE or SSW (Bitencourt, 1983) with

197 the 562 ± 8 Ma (SHRIMP U–Pb zircon - Remus et al., 2000) calc-alkaline Caçapava
198 Granite in its centre.

199 Three deformation events related to two metamorphic events were described in
200 the PFC (Bitencourt, 1983; Costa et al., 2021). The first two deformation events (D₁-
201 D₂) are progressive (Costa et al., 2021) and related to a ca. 570 Ma crustal thickening
202 episode, which is part of a long-lived transpressive deformation in the Dom Feliciano
203 Belt, starting at ca. 660–650 Ma (Battisti, 2022). The peak metamorphic conditions
204 (M₁) were estimated at 560–580 °C and 5–6.4 kbar (Costa et al., 2021; Battisti, 2022).
205 On the other hand, the M₂ metamorphic event is closely related to the emplacement of
206 the Caçapava Granite at ca. 562 Ma. According to Costa et al. (2021), the
207 crystallisation of andalusite marks the effect of contact metamorphism caused by the
208 Caçapava Granite during M₂–D₃.

209

210 ***2.5. Available geochemical and Sr-Nd isotopic data for the studied meta-*** 211 ***igneous rocks***

212

213 Geochemical studies of the Várzea do Capivarita Complex meta-igneous rocks
214 were performed by Martil et al. (2011, 2017). According to these authors, the ca. 790
215 Ma orthogneisses of the complex are metaluminous to peraluminous, calc-alkaline
216 rocks. Their composition and trace-element patterns are compatible with continental
217 arc-magmatism, with crustal contamination of parental magmas indicated by high
218 contents of Rb, Cs and Na₂O. This interpretation is corroborated by the isotopic studies
219 of Martil et al. (2017), which reveal $^{87}\text{Sr}/^{86}\text{Sr}_{(t)}$ ratios varying from 0.7163 to 0.7251 and
220 $\epsilon\text{Nd}_{(790)}$ values from –7.2 to –10.1 for these rocks. According to the same authors, the
221 atypical, high $^{87}\text{Sr}/^{86}\text{Sr}$ values and their variable inherited zircon ages of 3.1, 2.0, 1.8,
222 1.6, 1.1, and 1.0 Ga (Martil, 2016) confirm the re-working of older crust and are
223 consistent with their mature-arc signature.

224 Elemental geochemical studies of the Porongos Complex metavolcanics were
225 performed in its western (Marques et al., 1998, 2003; Gollmann et al., 2008) and
226 eastern (Saalman et al., 2006; Battisti et al., 2018) regions. On the other hand, Sr-Nd
227 isotopic studies are far more limited and comprise only a few samples with Sr isotopic
228 data included (Saalman et al., 2006; Martil et al., 2017). Nevertheless, the Porongos
229 Complex intermediate to acidic metavolcanic rocks (ca. 810–780 Ma) are assumed to
230 have formed in a continental magmatic arc (Gollmann et al., 2008; Battisti et al., 2018).

231 Among the samples from Western PC, three distinct groups of felsic rocks and
232 one group of mafic rocks were defined by Gollmann et al. (2008). However, the
233 presence of diachronous magmatic events (ca. 810-780 and 600 Ma) in the Porongos
234 Complex western region was not recognised at that time. Therefore, the meaning of
235 these different geochemical patterns remains unknown, as rocks associated with both
236 magmatic events might have been indistinctly compared. Moreover, no data has been
237 collected for the ca. 600 Ma Porongos magmatism.

238 Recent papers have suggested that part of the Porongos and Várzea do
239 Capivarita complexes may have shared similar sedimentary and volcanic history at
240 810–780 Ma (Martil et al., 2017; Battisti et al., 2018; De Toni et al., 2020b, 2021),
241 based on identical protolith ages, REE geochemistry and similar isotopic oxygen
242 signatures of meta-igneous rocks, structural evolution, and convergent PT-t evolution.
243 In addition, the overlapping Nd–Sr signatures of the VCC and one metavolcanic
244 sample of the PC Cerro da Árvore sequence was discussed by Martil et al. (2017).

245 Geochemical studies of the Passo Feio Complex meta-igneous rocks are rare
246 and focused only on the metabasic rocks so far (Bitencourt, 1983; Bicalho et al., 2019).
247 According to Bicalho et al. (2019), these basic rocks would have formed during a rifting
248 stage followed by an island arc situated in a restricted ocean environment. However,
249 the protolith ages of both basic and acidic Passo Feio metavolcanic rocks remain
250 unknown. Moreover, virtually no geochemical data has been published so far on the
251 intermediate to acidic metavolcanic rocks interleaved with the metasediments.

252

253 **3. MATERIALS AND METHODS**

254

255 **3.1. Data from the literature**

256

257 We have compiled published data for elemental and isotopic geochemical data
258 from metavolcanic rocks interleaved with the metasedimentary sequences from the
259 Passo Feio, Porongos, and Várzea do Capivarita complexes. The expressive majority
260 of data from Porongos and Várzea do Capivarita complexes display $\text{SiO}_2 > 55$ wt.%,
261 and such value was used as the lower threshold for the Passo Feio Complex samples.
262 Therefore, only intermediate to acidic metavolcanic rocks were considered in this
263 study. Samples with SiO_2 higher than 55 wt.% that lacked complete trace element data
264 were discarded, as those of Saalman et al. (2006). However, two samples from their
265 paper were kept based on two criteria: i) such samples represent the most studied

266 region of the Porongos Complex (Santana da Boa Vista region); ii) although
267 incomplete, Ce, Eu, Tb, Yb and Lu data are available for these samples.

268 Regarding isotope data, as different papers used different laboratories for Sr-Nd
269 analysis, we have double-checked all the isotopic calculations based on the
270 information available in the papers. The recalculated values for each sample are found
271 in Tables 1 and 2 (original values are provided in supplementary files). Samples with
272 similar recalculated values were maintained, but we have discarded samples with
273 strong discrepancies in the recalculated values. Such discarded samples are K-04C
274 (Table 1) and BR-152/1 (Table 2). Gollmann et al. (2008) reported only Nd isotopic
275 values, and therefore their data do not appear in diagrams considering $^{87}\text{Sr}/^{86}\text{Sr}$ at one
276 of the axes.

277

278 **INSERT TABLE 1**

279

280 **INSERT TABLE 2**

281

282 **3.2. Whole-rock geochemical analyses**

283

284 Elemental geochemistry data were obtained from four metavolcanic samples
285 from the Passo Feio Complex and one from the Porongos Complex. They were
286 analysed through inductively coupled plasma - optical emission spectrometry (ICP-
287 OES) and inductively coupled plasma mass spectrometer (ICP-MS) for major and trace
288 elements, respectively, at ActLab (Canada).

289

290 **3.3. Sm-Nd and Rb-Sr isotope determination**

291

292 Four of the abovementioned samples, in addition to two metavolcanic samples
293 from Battisti et al. (2018) and one from Martil et al. (2017), were selected for Sm-Nd
294 and Rb-Sr analyses. Thus, Sm-Nd and Rb-Sr isotope compositions were determined
295 in seven metavolcanic samples from the Passo Feio and Porongos complexes. Two
296 analyses were carried out at the Laboratory of Isotopic Geology of Universidade
297 Federal do Rio Grande do Sul (LGI-UFRGS). The other five analyses were carried out
298 at the Institute of Geology of the Czech Academy of Sciences (IG CAS). Detailed
299 analytical procedures are given available in Appendix 1.

300

3.4. *U-Pb LA-ICPMS geochronology*

Two samples from the Passo Feio Complex northern region were processed through a rock crusher and a hammer mill for the studied metavolcanic rocks. Zircon was separated using a Frantz™ isodynamic magnetic separator and heavy liquids at the Geosciences Institute of Universidade Federal do Rio Grande do Sul (UFRGS) laboratories. Subsequently, zircon grains were handpicked under a binocular microscope, and selected grains were mounted in one-inch epoxy disks and polished. In order to identify internal microstructures and possible compositional zoning, cathodoluminescence (CL) images of grains were made by JEOL EPMA housed at the Charles University in Prague. The zircon U–Pb LA-ICPMS isotopic dating was performed at the Institute of Geology of the Czech Academy of Sciences in Prague (see the detailed analytical conditions provided in supplementary material).

4. *RESULTS*

4.1. *Petrography of Porongos and Passo Feio metavolcanic rocks*

Seven metavolcanic samples were studied at systematic locations to gather a representative set of Porongos and Passo Feio rock types and fill the current gap of Rb-Sr and Sm-Nd isotopic data (Fig. 2). In addition, two samples from this set were selected for U–Pb geochronology (Fig. 3). The group comprises two samples from the Passo Feio Complex northern region and one from its southern region, two samples from the Eastern Porongos Complex region and two from the Western PC. The petrography of metavolcanic rocks is briefly summarised below.

i) Northern Passo Feio Complex region: Sample MF-174A is a grey metavolcanic rock from a rhyolitic layer in the metasedimentary package (Fig. 3a), with a poorly-developed foliation marked by feldspar porphyroclasts set in a fine-grained, granoblastic matrix and biotite-rich layers, with small amounts of white mica (Fig. 4a). Feldspar forms porphyroclasts up to 1.5 mm-long, mainly potassic in composition, with few plagioclase crystals. The feldspar often preserves igneous zoning at the centre, with recrystallised margins. Opaque minerals and zircon are accessories.

Sample MF-175A is a grey hypabyssal rhyolitic to dacitic rock from a boudinaged sill. It shows a weakly-deformed fabric (Fig. 3b) that displays a massif texture

336 composed of relic feldspar and quartz crystals set in a fine-grained granoblastic matrix
 337 containing green biotite (Fig. 4b). K-feldspar and quartz form up to 1.5 mm-long relic
 338 crystals. The matrix comprises granoblastic quartz and feldspar (Fig. 4b). Accessory
 339 minerals are chlorite, titanite, opaque minerals and zircon.

340

341

342

343 Figure 3. Outcrop features and location of samples from low-grade northern Passo Feio
 344 Complex dated with U-Pb LA-ICPMS in zircon: a) rhyolitic metavolcanic layer, and (b)
 345 metamorphosed and boudinaged sill of hypabyssal rhyolite.

346

347 **ii) Southern Passo Feio Complex region:** Sample MF-176B is a well-foliated
 348 granonematoblastic, grey metavolcaniclastic rock of andesitic/trachytic composition,
 349 with alternating irregular quartz-feldspathic and amphibole-rich seams (Fig. 4c). Up to
 350 1 mm-sized porphyroclasts of feldspar, commonly with deformed twins, and rarely
 351 quartz are preserved mainly in the fine-grained, quartz-feldspathic matrix. Opaque
 352 minerals and titanite are accessory phases.

353 **iii) Western Porongos Complex region:** sample MAB59A is a dark-green, low-
 354 grade meta volcaniclastic rock with a poorly-developed foliation. It is an albite-chlorite
 355 schist in which a fine-grained, opaque-chlorite-rich matrix surrounds albite-rich pockets

356 containing larger, angular crystals of albite with wavy extinction (Fig. 4d). Within the
 357 albite-rich pockets, some chlorite, opaque phases and rare apatite are also found. SEM
 358 studies confirm the absence of quartz from these rocks.

359 TM015A is a light-grey, foliated, rhyolitic metavolcaniclastic rock with narrow,
 360 alternating mica-rich lepidoblastic and quartz-rich, fine-grained levels and feldspar
 361 fragments up to 0.5 mm-long (Fig. 4e). Feldspar and quartz are often recrystallised in
 362 a fine-grained granoblastic matrix.

363

364

365

366 Figure 4. Petrographic aspects of the studied metavolcanic samples. Northern Passo Feio
 367 Complex (a) rhyolitic metavolcanic rock, (b) metamorphosed hypabyssal rhyolite; (c) Southern
 368 Passo Feio Complex metavolcaniclastic rock. Western Porongos Complex: (d) basic
 369 metavolcanoclastic rock and (e) rhyolitic metavolcanic rock (e). Eastern Porongos Complex
 370 rhyolitic metavolcanic rock (f) and (g). Mineral abbreviations (after Whitney and Evans, 2010):
 371 Qz – quartz, Fd –feldspar, Bt – biotite, Amp – amphibole, Ab – albite, Chl – Chlorite, Fe-Cb –
 372 Iron-carbonate, Ms – Muscovite.

373

374 **iv) Eastern Porongos Complex region:** Sample MAB05A is a well-foliated, grey
 375 blastoporphyritic metavolcanic rock containing up to 2 mm-long crystals of blue quartz

376 and rare feldspar in a fine-grained (0.05 mm), granolepidoblastic matrix (Fig. 4f). The
377 matrix comprises quartz, feldspar and biotite, the latter mostly in mm-thick, irregular
378 layers (Fig. 4f).

379 MAB09C is a grey metavolcanic rock with well-developed mylonitic foliation
380 marked by 1 mm-long blue quartz porphyroclasts (rare feldspar) in a fine-grained
381 granolepidoblastic matrix composed of white mica, quartz and feldspar (Fig. 4g). The
382 porphyroclast-rich levels alternate with white mica-rich layers, occasionally containing
383 also biotite and chlorite. Tiny amphibole crystals are found in the matrix and rarely in
384 the phyllosilicate-rich layers.

385

386 **4.2. Whole-rock chemistry and geochemical signatures of intermediate** 387 **to acidic metavolcanic rocks**

388

389 The measured whole-rock data for the metavolcanic rocks of this paper are
390 shown in Table 3. For the Passo Feio samples, SiO₂ ranges from 55.03 to 72.54 wt.%,
391 whereas for the Porongos Complex, SiO₂ are mainly from 67.00 to 71.74 wt.%. Such
392 values are in the range of the data selected from the literature for comparison (SiO₂ >
393 55 wt.%). The exception is sample MAB59A from western PC, which contains 52.4
394 wt.% silica, and the reason for maintaining it is its younger crystallisation age (600 Ma
395 – see discussion).

396

397 ***INSERT TABLE 3***

398

399 The new data collected within the framework of this study is supplemented by the
400 compiled data given as supplementary material. Altogether, the full dataset is
401 composed of four samples from the Passo Feio Complex (this paper), twenty-seven
402 samples from the Porongos Complex, whereby twelve from its eastern region
403 (Saalman et al., 2006; Martil et al., 2017; Battisti et al., 2018), and fifteen from the
404 western region (Gollmann et al., 2008; Martil et al., 2017), and twenty-four from the
405 Várzea do Capivarita Complex (Martil et al., 2017).

406

407 The whole set was analysed and grouped based on geochemical patterns, where
408 the REEs provide the best patterns chosen for grouping distinct samples. Each pattern
409 is placed in a *Group*, together with other distinctive geochemical characteristics, as
410 presented next. The REEs patterns normalised to Chondrite (Boyton, 1984) display
three contrasting distributions (Fig. 5a): i) *Group 1* characterised by LREE enrichment

411 over HREE ($\text{La}_N/\text{Yb}_N = \sim 10$) with largely negative Eu anomalies (Eu/Eu^* values mostly
412 from 0.38 to 0.86); ii) *Group 2* with enhanced LREE enrichment ($\text{La}_N/\text{Yb}_N = 12$ to 44)
413 compared to *Group 1* and no Eu anomaly ($\text{Eu}/\text{Eu}^* = 0.94$ to 1.07), and iii) *Group 3* with
414 negative Eu anomaly (Eu/Eu^* of ca. 0.70), but higher LREEs absolute values than
415 those found in groups 1 and 2 ($\text{La}_N/\text{Yb}_N = \sim 22$). Colour-labelled curves (Fig. 5) are
416 used to evaluate the role of SiO_2 content in groups 1 and 2 and demonstrate that SiO_2
417 variation is not responsible for the observed REE variability (Fig. 5a).

418 *Group 1* includes all samples from the eastern Porongos Complex region (Fig.
419 5b), eleven samples from the western Porongos Complex region (Fig. 5c), and all the
420 Várzea do Capivarita Complex samples (Fig. 5d). In comparison, *Group 2* comprises
421 five samples: two from the Passo Feio Complex northern region and three from the
422 Porongos Complex western region (Fig. 5a). The two samples from the PFC southern
423 region do not belong either to *group 1* or 2, and they were labelled as *Group 3* (Fig.
424 5a). Moreover, the basic metavolcaniclastic sample MAB59A from western PC will be
425 treated individually as a fourth pattern, referred to as *Bmvc*, as despite roughly
426 following *Group 2*, further trace element data show that it does not belong to any of the
427 three established groups.

428 In *Group 1*, SiO_2 ranges from 56.49 to 75.53 wt%. (Fig. 6); total alkali contents
429 ($\text{Na}_2\text{O} + \text{K}_2\text{O}$) are 3.58–8.23 wt%, $\text{K}_2\text{O}/\text{Na}_2\text{O}$ ratios range from 0.39 to 2.83 (with two
430 outliers of 18.1 and 23.7) and $\text{CaO}/(\text{Na}_2\text{O} + \text{K}_2\text{O})$ ratios lie between 0.06 and 1.23 (with
431 two outliers of 0.01 and 0.02). On the other hand, characterisation and assumptions
432 concerning *groups 2* and 3 need to be made with caution, considering the small
433 number of samples. Nevertheless, *Group 2* samples show a narrower SiO_2 range than
434 *Group 1*, from 63.07 to 72.54 wt% (Fig. 7). The total alkali contents ($\text{Na}_2\text{O} + \text{K}_2\text{O}$) are
435 5.76–8.14 wt%, $\text{K}_2\text{O}/\text{Na}_2\text{O}$ ratios vary from 0.21 to 0.63, and $\text{CaO}/(\text{Na}_2\text{O} + \text{K}_2\text{O})$ ratios
436 lie between 0.06 and 0.37. The two *Group 3* samples comprise the least evolved set
437 of samples, with SiO_2 at 55.03 and 55.12 wt% (Fig. 7), with total alkali contents (Na_2O
438 + K_2O) at 7.45 and 7.34 wt%, $\text{K}_2\text{O}/\text{Na}_2\text{O}$ ratios are from 0.20 to 0.21, and $\text{CaO}/(\text{Na}_2\text{O}$
439 + $\text{K}_2\text{O})$ ratios range between 0.74 and 0.75. *Bmvc* has $\text{SiO}_2 = 52.40$ wt.% (Fig. 7); total
440 alkali contents of 3.56 wt.%; $\text{K}_2\text{O}/\text{Na}_2\text{O}$ ratio of 0.06 and $\text{CaO}/(\text{Na}_2\text{O} + \text{K}_2\text{O})$ ratio of
441 0.46.

442

443

444 Figure 5. Rare Earth Element fractionation patterns normalised by chondrite (Boyton, 1984).

445 A) Comparison of REE data of groups 1 (pink box), 2, 3 and Bmvc. *Group 1* consists of samples

446 from (b) eastern, and (c) western regions of the Porongos Complex and from (d) Várzea do

447 Capivarita Complex. E) REE patterns for metavolcanic samples with available crystallisation

448 ages are highlighted. Colour-coded curves indicate SiO_2 content in all plots.

449

450

451 Figure 6. Major and some trace element variation diagrams using SiO_2 as differentiation index
 452 for *Group 1* metavolcanic rocks. Major elements in wt% and trace elements in ppm. Colour-
 453 code indicates SiO_2 content as in figure 5.

454

455 In the Harker diagrams for *Group 1* (Fig. 6), TiO_2 , Al_2O_3 , MgO , CaO and FeO_t
 456 decrease when SiO_2 content increases, whilst K_2O and Na_2O do not show any
 457 correlation. Regarding trace elements, Rb , La , Ce and Y show a slight increase in the
 458 more differentiated samples; Ba and Sr have moderate to low contents and do not
 459 correlate with differentiation. Zirconium shows moderate contents, increasing in the
 460 Western Porongos more differentiated samples. The $\text{K}_2\text{O}/\text{Na}_2\text{O}$ values range between
 461 ~1 and 2 and do not vary with differentiation; two high- SiO_2 samples show high ratios.
 462 Harker diagrams for *Group 2* samples (Fig. 7) indicate a decrease of TiO_2 , Al_2O_3 , MgO ,
 463 CaO , K_2O and FeO_t when SiO_2 content increases, whilst an opposite trend is noticed
 464 for Na_2O . Despite the low number of samples, a negative correlation between Zr , Rb
 465 and Y versus SiO_2 can be pointed out. Other trace elements do not show clear trends
 466 in the Harker diagrams. The two *Group 3* samples and the *Bmvc* were plotted together

467 with those of *Group 2* in Harker diagrams (Fig. 7) for further comparison of the data.
 468 Their very contrasting Ca, Sr, and Zr contents, not justified by magmatic differentiation,
 469 together with their different REE patterns and the lack of correlation in most trace-
 470 element diagrams, indicate that *groups 2* and *3* samples do not belong to the same
 471 magmatic series. Therefore, using the same criteria, it is possible to state that *Bmvc*
 472 does not belong to any of the above groups.
 473

474
 475

476 Figure 7. Major and some trace-element variation diagrams using SiO_2 as differentiation index
 477 for *Group 2* metavolcanic rocks (coloured forms), *3* (black squares) and *Bmvc* (grey circle).
 478 Data for these three different groups were plotted together to compare the data (see
 479 discussion). Major elements in wt% and trace elements in ppm. Colour-code indicates SiO_2
 480 content as in figure 5.

481

482 Samples from *groups 1* and *2* are mostly dacites and rhyolites in the diagram of
 483 Le Bas et al. (1986) (Fig. 8a, b). According to the same diagram, *Group 3* samples are
 484 classified as trachy-andesites, and *Bmvc* as basaltic andesite. Because mobilisation

485 of elements such as LILE and Na during metamorphism can happen, we have
 486 employed some classification diagrams based on the ratios of relatively immobile
 487 elements, for instance, Zr/TiO_2 versus Nb/Y and SiO_2 versus Zr/TiO_2 (Winchester and
 488 Floyd, 1977). As shown in Fig. 8a, the resulting plots for *Group 1* samples corroborate
 489 the TAS results (Le Bas et al., 1986) since most samples (36 from 47) are classified as
 490 dacite to rhyodacite, suggesting that metamorphism did not significantly change their
 491 alkali contents. The same was observed for *Group 3* samples (Fig 8b). All *Group 2*
 492 samples show different classification in Winchester and Floyd (1977) compared to the
 493 TAS diagram (Fig 8b). Such data may indicate a significant change in alkali contents
 494 during the metamorphism of *Group 2* samples. *Bmvc* also displays a different
 495 classification, as it plots into the field of alkali-basalt (Fig 8b).
 496

497

498

499 Figure 8. Discrimination diagrams for the studied metavolcanic rocks. At the top TAS diagram
 500 of Le Bas et al. (1986) for Group 1 rocks (a), groups 2, 3 and Bmvc (b). At the bottom,
 501 Winchester and Floyd's (1977) diagrams based on the ratios of relatively immobile elements
 502 for Group 1 (a) and groups 2, 3 and Bmvc (b).

4.3. Zircon U-Pb geochronology

503

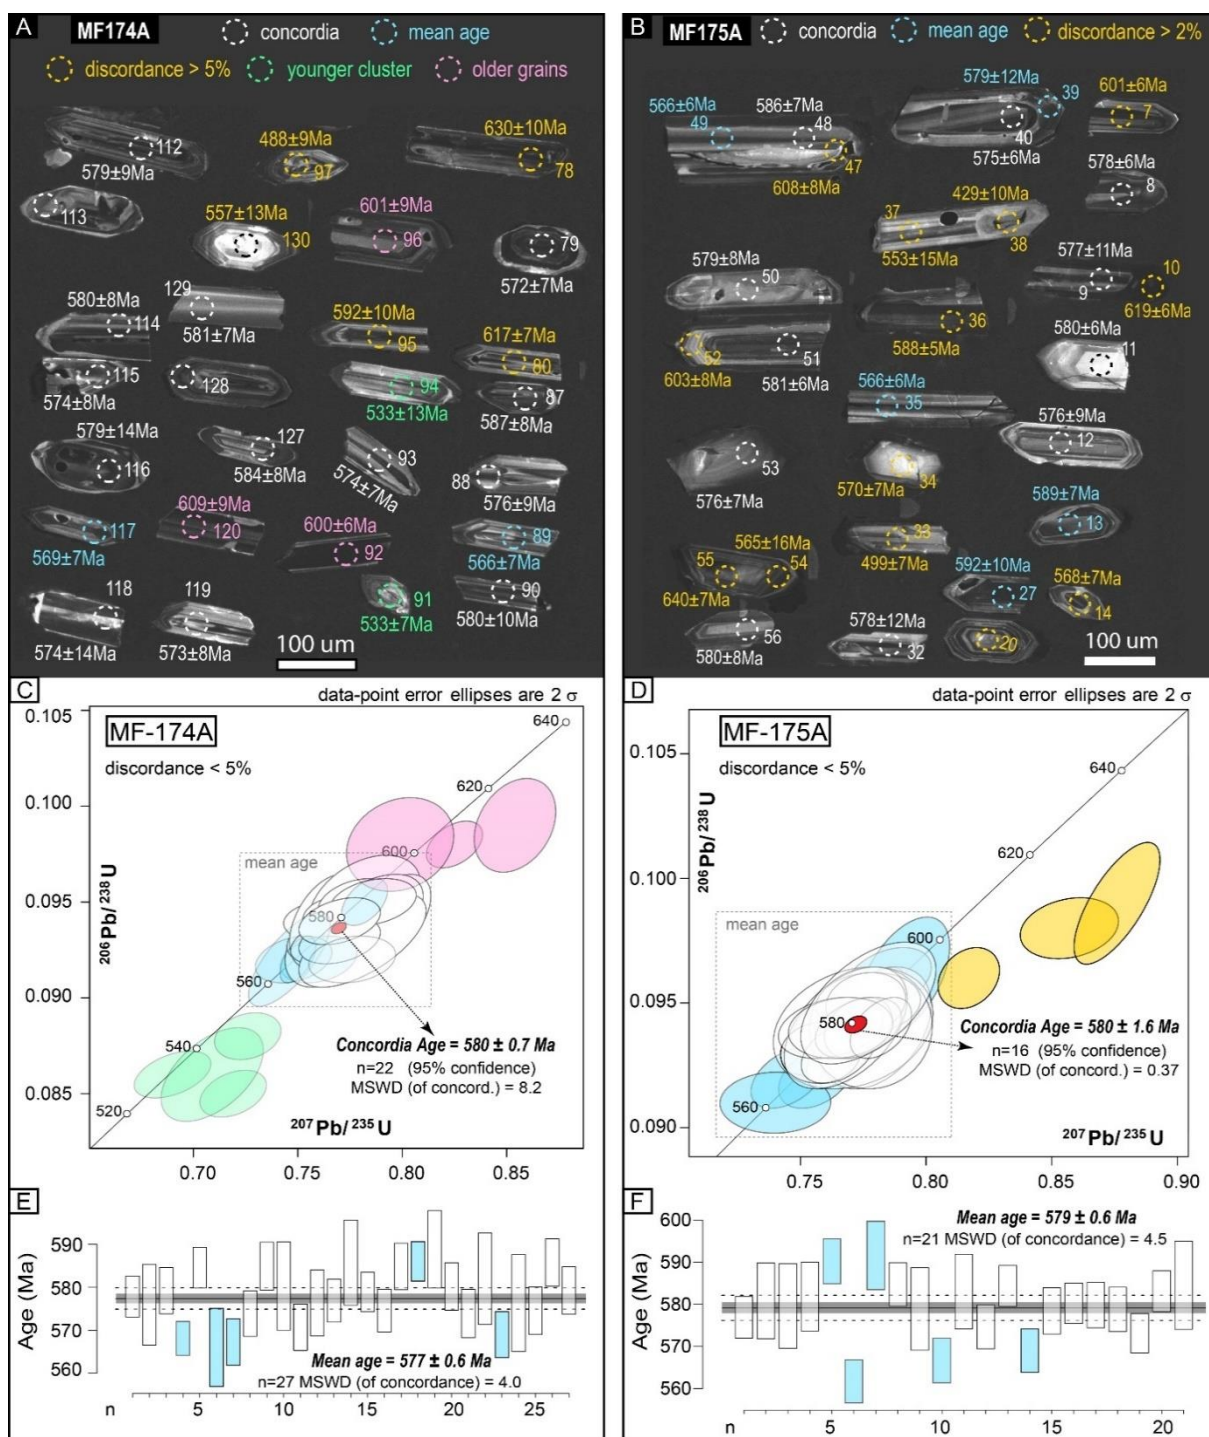

504

505 U-Pb LA-ICPMS geochronological data were obtained in two acidic metavolcanic
506 samples of *Group 2* from the northern Passo Feio Complex to constrain their protolith
507 ages for the first time. Furthermore, as these rocks make up deformed lenses
508 surrounded by metapelitic rocks, they may also help constrain the timing of the main
509 deformation of the complex (Fig. 3a, b).

510

511 In sample MF174A, the zircon population is rather homogeneous. The grains are
512 euhedral to subhedral with shapes ranging from stubby, almost equidimensional
513 prisms to often more elongated prismatic forms (Fig. 9a) with sizes of ca. 50–200 μm .
514 Cathodoluminescence (CL) imaging reveals that well-developed oscillatory zoning
515 dominates internal structures. Few grains show complex zoning patterns in the core
516 (spot #107 and #116 – all spots are given in Supplementary data). However, the ages
517 obtained are similar to those from the oscillatory zoning (Fig. 9c). Forty-four analyses
518 were performed in forty-four different zircon grains, and in this dataset, thirty-four spots
519 represent the most concordant analyses (discordance < 5% - Fig. 9c). A cluster of
520 twenty-seven spots produces a mean age of 577 ± 1 Ma (2σ) (Fig. 9e) and presents
521 Th/U ratios ranging from 0.49 to 2.06 (Supplementary data). Discarding the outlier
522 values of such mean age (blue rectangles in Fig. 9e), twenty-two spots define a
523 concordia age of 580 ± 1 Ma (2σ), which is very similar to the mean age of the cluster
524 (Fig. 9c). Thus, the concordia age is interpreted as the best estimate for the
525 crystallisation of the metavolcanic protolith. Four spots with younger ages (#74, #91,
526 #94, #98) and three with older ages (#92, #96, #120) have discordance lower than 5%,
527 and they occupy the ages of ca. 540 Ma (green ellipses) and ca. 600 Ma (pink ellipses),
528 respectively. Despite their similarity in Th/U ratios (0.57 to 2.07), the younger zircon
529 grains show an internal striped zonation that strongly indicates perturbation of U–Pb
530 systematics. Thus, we interpret these four younger ages as a consequence of Pb loss.
531 We also observe some discordance for the three older grains, all obtained in central
532 parts of euhedral grains, representing older grains with Pb loss or other U–Pb system
533 disturbance.

533

534

535

536 Figure 9. Cathodoluminescence images of representative zircon grains from sample MF-174A
 537 (a) and MF-175A (b) (ages are given as $^{206}\text{Pb}/^{238}\text{U}$ – complete information is available in
 538 Supplementary data). Concordia U–Pb diagram with less than 5% discordance zircon crystals
 539 for MF-174A (c) and MF-175A (d). Colour-coded spots distinguish each LA-ICPMS spot in
 540 zircon grains shown in (a) and (b), respectively. The concordia age is interpreted as the
 541 crystallisation age of both samples. The $^{207}\text{Pb}/^{206}\text{Pb}$ mean age for the main cluster centred at
 542 ca. 580 Ma in MF-174A (e) and MF-175A (f), the spots in blue were discarded for the
 543 calculation of concordia age in (c) and (d), respectively.

544 Zircon from sample MF175A has similar characteristics as in sample MF174A.
545 The zircon population is also rather homogeneous, and the grains are euhedral to
546 subhedral with elongate prismatic shapes and crystal sizes at ca 100–300 μm (Fig. 9b)
547 with well-developed oscillatory zoning observed in CL. However, acquired ages do not
548 vary through the oscillatory zoning regions (Fig. 9d). Forty-two analyses were
549 performed in thirty-three different zircon grains, and the most concordant analyses
550 (discordance < 5%) were displayed in a Wetherill U–Pb diagram (all spots are available
551 in Supplementary material). Such dataset comprises twenty-four spots, in which
552 twenty-one define a cluster with a mean age of 579 ± 1 Ma (2σ) and Th/U ratios from
553 0.29 to 1.55 (Fig. 9d, f). Discarding the outlier values of such mean age (blue
554 rectangles in Fig. 9f), sixteen spots define a concordia age of 580 ± 2 Ma (2σ), which
555 is very similar to the cluster mean age, and it is interpreted as the best estimate for
556 crystallisation of the metavolcanic protolith (Fig. 9d).

557

558 **4.4. Sr and Nd isotopic compositions**

559

560 The Sr-Nd isotopic data obtained for the studied metavolcanic rocks from Passo
561 Feio and Porongos complexes are given in Table 4. In the Passo Feio Complex, the
562 acidic to intermediate metavolcanic rocks show slight differences in Sr-Nd values when
563 comparing the northern (NPFC, 580 Ma) and southern (SPFC, 580 Ma) regions. The
564 ca. 580 Ma crystallisation age of the NPFC metavolcanic protolith was described
565 above. The acidic metavolcanic rocks from NPFC (580 Ma) have restricted and low
566 $^{87}\text{Sr}/^{86}\text{Sr}_t$ values of 0.7041 – 0.7035 and ϵNd_t ca. -10, with Mesoproterozoic TDMs
567 (1555 – 1579). On the other hand, the intermediate metavolcanic rock from SPFC,
568 whose age is still unknown but also estimated in 580 Ma for calculation purposes
569 (which is the only known age for the metavolcanic rocks in the complex), have slightly
570 higher $^{87}\text{Sr}/^{86}\text{Sr}_t$ values of 0.7064 and less negative ϵNd_t of -2.1, with Mesoproterozoic
571 TDM as well (1235 Ma).

572

573 The Porongos Complex Sr-Nd values are more homogeneous when considering
574 the Eastern (EPC, 790 Ma) and Western (WPC, 790 or 600 Ma) regions. The acidic
575 metavolcanic rocks from the EPC have high $^{87}\text{Sr}/^{86}\text{Sr}_t$ values of 0.7248 to 0.7305 and
576 ϵNd_t ca. -10, with Paleoproterozoic TDMs (2019 – 2080 Ma). In contrast, the WPC
577 samples comprise one acidic metavolcanic rock with 790 Ma that has $^{87}\text{Sr}/^{86}\text{Sr}_t$ values
578 of 0.7083, ϵNd_t -6.2 and Paleoproterozoic TDM of 1822 Ma; and one basic
metavolcaniclastic rock with 600 Ma (Höfig et al., 2018) with contrasting $^{87}\text{Sr}/^{86}\text{Sr}_t$

579 values of 0.7065, $\epsilon\text{Nd}_t +1.2$, and Neoproterozoic (Tonian) TDM of 1079 Ma. The
580 contrasting Sr-Nd isotopic values of the basic metavolcaniclastic (*Bmvc*) sample are
581 consistent with mantle-derived source rocks and also consistent with its
582 metavolcaniclastic origin, low SiO₂ content and the data from Höfig et al. (2018), which
583 present a nearly unimodal provenance peak of 600 Ma. Therefore, considering the
584 entire dataset permits us to interpret this sample as part of the WPC basic magmatism.

585 The new data were compared with data available in the literature for the PC and
586 VCC since there are no other data for PFC. The complete dataset will be integrated in
587 the Discussion section. A summary of the U–Pb dating and Sr-Nd isotopic results
588 obtained in this paper with sampling coordinates is shown in table 5.

589

590 ***INSERT TABLE 4***

591

592 ***INSERT TABLE 5***

593

594 **5. DISCUSSION**

595

596 **5.1 Significance and implications of elemental and isotopic** 597 **geochemical data for the studied complexes**

598

599 In the set of forty-seven *Group 1* samples, igneous crystallisation ages are known
600 for two Várzea do Capivarita Complex samples and two Porongos Complex eastern
601 region samples. They vary between ~810 and 780 Ma (Saalman et al., 2011; Martil
602 et al., 2017; Battisti, 2022). As shown in Fig. 5e, these four specimens are probably
603 related to the same magmatic event, as indicated by their similar geochemistry, in
604 addition to the similar crystallisation ages and geological field relations. The
605 geochronological data from this study point out that the Passo Feio Complex *Group 2*
606 samples have a crystallisation age of 580 Ma. Three other *Group 2* samples are from
607 the western PC region, and their crystallisation ages are unknown. Such lack of data
608 in the western PC region also indicates that assumptions concerning *Group 2* samples
609 must be made with caution. The two *Group 3* samples are also of unknown age, whilst
610 the individual *Bmvc* has an igneous age of 600 ± 7 Ma (Höfig et al., 2018 – Fig.
611 5e).

612 Based on this assumption, Sr-Nd data from *Group 1* rocks were recalculated to
613 initial isotopic ratios based on a crystallisation age of 790 Ma (Fig. 10). Aiming at a

614 consistent comparison, the original Sr-Nd data from Gollmann et al. (2008) and
 615 Saalman et al. (2006) were recalculated to 790 Ma (Table 1 and 2). On the other
 616 hand, for *Group 2* rocks, Sr-Nd data were calculated using a crystallisation age of 580
 617 Ma. Due to the geographical proximity (see Fig. 2) with this group, samples from *Group*
 618 3 were also calculated for 580 Ma, as no other crystallisation age is known for the
 619 metavolcanic rocks of the region. For the individual basic metavolcanoclastic rock
 620 (*Bmvc*), the value used for isotope calculations was 600 Ma based on the age obtained
 621 by Höfig et al. (2018).

622

623

624

625 Figure 10. Whole-rock Rb–Sr and Sm–Nd isotope data for the Passo Feio, Porongos and
 626 Várzea do Capivarita complexes meta-igneous rocks: (a) ϵNd_t relative to $^{87}Sr/^{86}Sr_t$; (b) ϵNd_t
 627 relative to SiO_2 ; (c) $^{87}Sr/^{86}Sr_t$ relative to SiO_2 ; and (d) ϵNd_t relative to TDM.

628

629 In *Group 1* rocks, $^{87}Sr/^{86}Sr_{(790\text{ Ma})}$ values exhibit a wide range for the PC samples
 630 (0.7083–0.7305) and a narrower range for VCC (0.7163 and 0.7251). The $\epsilon Nd_{(790\text{ Ma})}$
 631 values are mainly between -5 and -11 for both PC and VCC. However, $\epsilon Nd_{(790\text{ Ma})}$
 632 values as high as -2 and as low as -22 are found only in the PC samples. Such
 633 $^{87}Sr/^{86}Sr_{(790\text{ Ma})}$ values higher than 0.715 and $\epsilon Nd_{(790\text{ Ma})}$ mainly from -5, and -11 (up to
 634 -22) indicate an important contribution of crustal materials due to crustal melting or
 635 assimilation of host rocks for the VCC and PC region ca. 790 Ma metavolcanic rocks.

636 However, two *Group 1* samples have slightly lower $^{87}\text{Sr}/^{86}\text{Sr}_{(790\text{ Ma})}$ - BR-143/1 and TM-
637 015, with 0.7106 and 0.7083, respectively. Such low values may indicate that crustal
638 contamination may have had some spatially-controlled variation in the PC or that the
639 ca. 790 Ma magmatism had different amounts of mantle contribution in different
640 regions, as BR-143/1 and TM-015 come from the eastern and western Porongos
641 regions, respectively.

642 The integration of geochronological, geochemical and Sr-Nd isotopic data allows
643 us to consider that *Group 1* samples belong to the same magmatic event, i.e., they are
644 probably coeval and produced by melting of the same sources at 810-780 Ma. The
645 relatively high Al_2O_3 contents of intermediate to acidic *Group 1* rocks, their subalkaline
646 character, trends illustrated in the FMA diagram, and the K_2O contents (Fig. 11a)
647 indicate that they are part of a medium- to high-K calc-alkaline series. Furthermore,
648 the REE patterns and trace elements are coherent with the hypothesis of *Group 1*
649 rocks representing magmatic associations produced from subduction-related sources,
650 probably along active continental margins (e.g. Martil et al., 2017), as suggested by
651 relatively high K_2O and Sr contents and by trace elements in Fig. 12a. Therefore, such
652 observations are coherent with the Sr-Nd data, which suggest an important
653 contribution of crustal materials for *Group 1* rocks. Lastly, when compared to OIB
654 (Oceanic Island Basalts), *Group 1* spidergrams (Fig. 13) show enrichment in LILE and
655 LREE relative to HFSE (Na, Ta, Hf, Zr) and HREE. In addition, Nb-Ti-Ta-P negative
656 anomalies are present in all samples from this group, which is a well-known signature
657 inherited from subduction-related sources (e.g. Briquet et al., 1984; Pearce, 1995).

658 In *Group 2*, PFC samples exhibit $^{87}\text{Sr}/^{86}\text{Sr}_{(580\text{ Ma})}$ values of 0.7035 and 0.7041,
659 and $\epsilon\text{Nd}_{(580\text{ Ma})}$ values of -10, whilst PC samples show variable $\epsilon\text{Nd}_{(580\text{ Ma})}$ values of -
660 13, -14 and -21 (no Sr data). The only analysed *Group 3* specimen displays $^{87}\text{Sr}/^{86}\text{Sr}_{(580\text{ Ma})}$
661 of 0.7050 and $\epsilon\text{Nd}_{(580\text{ Ma})} = -2$. The *Bmvc* presents $^{87}\text{Sr}/^{86}\text{Sr}_{(600\text{ Ma})}$ equal to 0.7065
662 and $\epsilon\text{Nd}_{(600\text{ Ma})} = +1$. Such values indicate that at least part of these rocks are related
663 to mantle-derived sources, with absent or low crustal assimilation, except for the ones
664 with strongly negative $\epsilon\text{Nd}_{(580\text{ Ma})}$ values for which $^{87}\text{Sr}/^{86}\text{Sr}_{(580\text{ Ma})}$ data are not available
665 for further evaluation.

666 We emphasise that rocks of *Groups 2* and *3* are represented by few samples,
667 which do not permit us to fully explore the nature of magmas, sources, and geotectonic
668 settings. Nevertheless, their moderate to high Al_2O_3 contents, subalkaline character,
669 and trends observed in the FMA diagram (Fig. 11b), together with their K_2O contents,
670 suggest their close relationship to acidic rocks of medium-K calc-alkaline series, or

671 magmatism with a strong crustal contribution. In addition to high Sr contents, such
 672 aspects point out a subduction-related source for *groups 2* and *3* rocks. However, Sr-
 673 Nd isotopic data suggest that at least part of *groups 2* and *3* rocks are related to mantle-
 674 derived sources. Additional trace element diagrams based on Nb, Ta and Y suggest a
 675 rather volcanic arc environment for *Group 2* rocks (Fig. 11b). On the other hand, *Bmvc*
 676 has low Al_2O_3 content and high MgO and FeO_t contents, characteristic of the tholeiite
 677 series, as indicated by the FMA diagram.

681 Figure 11. SiO_2 x K_2O diagram (modified from Peccerillo and Taylor, 1976), at the top; for
 682 Group 1 (a), and groups 2, 3 and Bmvc (b). At the bottom, AFM diagram (modified after Irvine
 683 and Baragar, 1971) for Group 1 (a) and groups 2, 3 and Bmvc (b).

684

685

686

687 Figure 12. Tectonic setting discriminant diagram for granitoids from Pearce et al. (1984)
 688 applied to *Group 1* (a) and *Group 2*, (b) acidic metavolcanic rocks. Diagrams containing Rb
 689 were excluded due to the high mobility of this element.

690

691 When compared to OIB, *groups 2* and *3* present more discrete LILE and LREE
 692 enrichment over HREE and HFSE, although both group patterns display Nb-Ta
 693 negative anomalies, which suggest a subduction-related magmatic source. It is
 694 important to point out that Ti and P anomalies are expected for intermediate to acidic-
 695 rocks (as in *groups 1, 2* and *3*) due to magmatic differentiation and irrespective of the
 696 magmatism geological setting. *Bmvc*, when compared to OIB, does not display Nb, Ta,
 697 P and Ti negative anomalies. Together with the probable tholeiitic affinity of this
 698 sample, such characteristics suggest it is not a product of sources affected by
 699 subduction-related metasomatism. However, it is important to point out that *Bmvc*

700 LREE content is higher than expected for tholeiitic rocks, which indicates that
 701 contamination or assimilation processes cannot be ruled out.
 702

703

704

705 Figure 13. Spidergrams normalised by Oceanic Island Basalts (OIB – Sun and McDonough,
 706 1989) for groups 1, 2, 3 and *Bmvc*.

707

708 When considering the correlations of $^{87}\text{Sr}/^{86}\text{Sr}_t$ values, ϵNd_t values and SiO_2
 709 contents, as shown in figure 10, we can see that *groups 2 and 3* (580 Ma) and some
 710 least differentiated samples from *Group 1* (790 Ma) show lower $^{87}\text{Sr}/^{86}\text{Sr}_t$ values (<
 711 0.7100) and variable ϵNd_t (+2 to -10) which suggest mantle contribution with variable
 712 amounts of crustal contamination. On the other hand, most of *Group 1* samples (790
 713 Ma) show the highest $^{87}\text{Sr}/^{86}\text{Sr}_t$ values (> 0.7100) and negative ϵNd_t (-10) besides the
 714 strong positive correlation between $^{87}\text{Sr}/^{86}\text{Sr}_t$ values and SiO_2 contents, suggesting
 715 strong crustal contamination potentially correlated to assimilation and crustal
 716 contamination processes (AFC).

717

718

719 **5.2 Timing and geotectonic setting of the magmatic events in the Passo**
720 **Feio, Porongos, and Várzea do Capivarita complexes**

721

722 Combined major and trace element data and Sr-Nd isotopes with U–Pb
723 geochronology can be used to constrain the temporal evolution of the magmatic events
724 in metavolcanic rocks from ancient basins. According to previous studies and new
725 geochronological data, the intermediate to acidic meta-igneous rocks discussed in this
726 paper may be grouped into two diachronous episodes of magmatism, one at ca. 810–
727 780 Ma and the other at ca. 600–580 Ma (Fig. 6e). The ca. 810–780 Ma magmatic
728 event is documented in the PC (Saalman et al., 2011; Pertille et al., 2017; Battisti,
729 2022) and VCC (Martil et al., 2017; Battisti, 2022). Samples belonging to this magmatic
730 event fit into *Group 1* samples derived from subduction-related sources with strong
731 crustal contribution, probably associated with AFC processes, as evidenced by Sr-Nd
732 isotopic and geochemical data. If mantle contribution would be considered at this time,
733 it should be minor, and the geochemical and isotopic signatures of such mantle source
734 contribution are diluted. Such characteristics are very common along active continental
735 margins, as in Andean-type mature arcs. Thus, this is the environment suggested for
736 the generation of the ca. 780–810 Ma Porongos and Várzea do Capivarita
737 orthometamorphic rocks. Our interpretation corroborates previous studies dealing with
738 major/trace elements (Martil et al., 2017; De Toni et al., 2020b) as well as Sr-Nd
739 systematics (Martil et al., 2017) and oxygen isotopic composition of zircon (Battisti,
740 2022). However, the nature of this magmatism is still a matter of debate, as other
741 authors interpret it as back-arc/rift magmatism (Konopásek et al., 2018; Will et al.,
742 2019).

743 The 600–580 Ma magmatism is documented in the western Porongos region
744 (Zvirtes et al., 2017; Höfig et al., 2018) and in the Passo Feio Complex (this paper).
745 Sample MAB59A (*Bmvc*) represents this younger magmatism in the Porongos
746 Complex. Moreover, *Group 2* Porongos metavolcanic rocks display a strong
747 geochemical similarity with the ca. 580 Ma PFC metavolcanic rocks, which suggests
748 they are also part of this Ediacaran magmatism. Thus, considering the small number
749 of samples, our restricted data suggests coeval magmatism within ca. 600–580 Ma
750 between northern PFC and western PC.

751 The unknown crystallisation age, in addition to a different geochemical pattern,
752 makes it difficult to estimate the timing of *Group 3* magmatism from southern PFC.
753 However, in the absence of further geochronological data from this complex, it is

754 strongly possible that *Group 3* magmatism also sits around ca. 600–580 Ma, as the
755 northern PFC magmatism. Dating based on Lu-Hf isochron in garnet from the southern
756 PFC metapelites interleaved with the studied metavolcanic rocks places the event
757 which deformed the whole package at 571 ± 13 Ma (Battisti, 2022). Thus, *Group 3*
758 magmatism ought to have happened before ca. 570 Ma, very likely at ca. 600–580 Ma.

759 At 600–580 Ma, no magmatism is registered in the *Várzea do Capivarita*
760 Complex, or eastern region of *Porongos Complex*, although rocks of such age are
761 reported in the western *Porongos* region and *Passo Feio*, as discussed above. *Groups*
762 *2* and *3* rocks and *Bmvc* possibly belong to coeval magmatism, but they have specific
763 characteristics. Elemental geochemistry suggests subduction-related sources for
764 *groups 2* and *3*, but not clearly for the *Bmvc*. However, differently from *Group 1* rocks,
765 elemental geochemistry and Sr-Nd isotopic data suggest less evolved sources for
766 *groups 2* and *3* magmatism, i.e., mantle-derived sources. Such data might indicate that
767 a subduction-related enriched mantle generated *groups 2* and *3* rocks with minor
768 crustal contribution. A back-arc scenario at ca. 600–580 Ma would be a possible
769 environment to generate rocks with such characteristics. The *Bmvc*, however, has
770 different geochemical aspects relative to *groups 2* and *3*. In this sample, both elemental
771 and Sr-Nd isotopic data suggest a mantle-derived origin without significant contribution
772 of subduction-related sources, crustal melting, and contamination, even though LILEs
773 are somewhat higher than expected for tholeiitic rocks. Such differences in *Bmvc* may
774 also have been caused by heterogeneities in the mantle source of the Ediacaran
775 magmatism.

776

777 **5.3 Geological relations between *Passo Feio*, *Porongos* and *Várzea do*** 778 ***Capivarita* complexes**

779

780 The *Várzea do Capivarita Complex* is traditionally interpreted as the granulitic
781 basement of the *Dom Feliciano Belt* intruded by Neoproterozoic granites (Gross et al.,
782 2006; Martil et al., 2011), although the real age of the complex was unknown. Recent
783 studies (Martil, 2016) revealed that the crystallisation age of meta-igneous rocks
784 tectonically interleaved with the metasedimentary VCC sequence is ca. 790 Ma. Such
785 age is the same as the traditionally known *Porongos Complex* metavolcanic rocks
786 (Saalman et al., 2011; Pertille et al., 2017) and is also found in other regions of the
787 *Dom Feliciano Belt* (Koester et al., 2016; De Toni et al., 2020b). Thus, after the paper
788 of Martil (2016), the synchronicity of the magmatism and sedimentation between these

789 high- and low-grade metamorphic complexes was explored by several authors (e.g.
790 Battisti et al., 2018; De Toni et al., 2020b), which concluded that they had shared
791 volcano-sedimentary sources at ca. 790 Ma. Such interpretation is corroborated by the
792 geochemical similarities found among the studied *Group 1* rocks.

793 However, the geological history of the Porongos Complex is indeed complex. For
794 example, Höfig et al. (2018) demonstrated that besides the ca. 810–780 Ma
795 magmatism, a magmatic event of ca. 600 Ma was also registered in Porongos, which
796 is related to a completely different geological evolution (Battisti, 2022). Based on this,
797 Battisti (2022) proposed that the Porongos Complex would have to be treated as two
798 individual sequences called Cerro da Árvore and Capané.

799 The Cerro da Árvore sequence (CAs) is the oldest Porongos sequence and
800 comprises metasedimentary rocks interleaved with ca. 810–780 Ma meta-igneous
801 rocks. This sequence is the part of the Porongos Complex that can directly correlate
802 with the Várzea do Capivarita Complex. Both CAs and VCC sediments were deposited
803 before ca. 810 Ma, as indicated by the crystallisation age of the associated
804 metavolcanic rocks in both complexes (Saalman et al., 2011; Pertille et al., 2017),
805 until < ca. 660–650 Ma, when the collisional setting took place, as registered by
806 metamorphic ages found in both complexes (Chemale et al., 2011; Martil, 2016,
807 Battisti, 2022). Most of the PC metavolcanic rocks discussed in this paper fall into
808 geochemical *Group 1*, indicating that the 810-780 Ma magmatism is the most
809 expressive and widespread in the Porongos Complex (both eastern and western
810 regions).

811 The Capané sequence is the younger one and comprises metasedimentary rocks
812 deposited in the western region of the Porongos Complex at an unspecified time
813 between ca. 660 to ca. 560 Ma (Pertille et al., 2015, 2017; Höfig et al., 2018), with
814 contemporaneous ca. 600 Ma meta-igneous rocks (Zvirtes et al., 2017; Höfig et al.,
815 2018). PC *Group 2* and *Bmvc* rocks are part of the igneous event of this sequence,
816 exclusively found in the western Porongos Complex region. However, their
817 geochemical differences indicate that the Capané sequence magmatism (600-580 Ma)
818 was probably complex and demands further studies.

819 Moreover, based on geochemical and Sr-Nd isotopic data, the ca. 600 Ma
820 magmatism (to possibly 580 Ma) in the Capané sequence can be related to the
821 magmatism in the northern PFC, as rocks of both complexes bear *Group 2* features.
822 Also, the comparison can be extended to the southern PFC magmatism in a less
823 straightforward interpretation. Such data point to the PC and PFC as sharing margins

824 at 600–580 Ma, which corroborates the interpretation that the PC Capané sequence
825 and the PFC were deformed together at ca. 570–565 Ma (Battisti, 2022). According to
826 the same authors, such ca. 570-565 Ma deformation records a front migration towards
827 the west of a long-lived transpressive deformation, which started at ca. 660-650 Ma,
828 as registered in the Porongos Cerro da Árvore sequence and Várzea do Capivarita
829 Complex. Thus, it is possible to state that the geological evolution of Passo Feio,
830 Porongos, and Várzea do Capivarita complexes are at some point all connected.

831

832 **5.4 Is the generation of a back-arc setting at ca. 600-580 Ma a space** 833 **problem?**

834

835 The ca. 600–580 Ma magmatic rocks of Porongos and Passo Feio complexes
836 were emplaced between two events of crustal thickening in the central Dom Feliciano
837 Belt foreland (660 and 565 Ma – Battisti, 2022 – Fig. 14). However, such metavolcanic
838 rocks do not show significant crustal contribution, suggesting that they were emplaced
839 in a geological scenario of attenuated crust. Moreover, it is important to point out that
840 an extensive 630–580 Ma post-collisional batholith is situated only some kilometres
841 east of the studied area, which indicates magmatism was going on all over the Dom
842 Feliciano Belt at that time (Fig 14).

843 Studies carried out in undeformed sedimentary basins neighbouring the Passo
844 Feio and Porongos complexes demonstrated back-arc stratigraphy for 630–600 Ma
845 units (Borba et al., 2008; Almeida et al., 2012; Paim et al., 2014) and transtentional
846 position for the 595–580 Ma units (Janikian et al., 2008, 2012; Paim et al., 2014) in
847 such basins. The stratigraphic record of these basins demonstrates that local spaces
848 have been created in the Dom Feliciano Belt foreland from 630–580 Ma, and a similar
849 situation might have happened in the western Porongos Complex region and Passo
850 Feio Complex. For some reason still unexplained, the rocks of such sedimentary
851 basins remained undeformed during the ca. 565 Ma crustal thickening event that
852 deformed and metamorphosed the Passo Feio Complex and the western region of
853 Porongos Complex.

854 Thus, the emplacement of the Ediacaran magmatism of Passo Feio and western
855 Porongos region in a back-arc scenario does not pose a structural problem.
856 Alternatively, a transtensive basin is suggested as a possible scenario, as drawn in
857 figure 14. Both scenarios would be in accordance with the reported geochemical and

858 isotopic signatures and would fit geometrically with the contemporaneous undeformed
 859 volcano-sedimentary basins of the Dom Feliciano Belt foreland.
 860

861

862

863 Figure 14. Evolutionary model of Porongos, Várzea do Capivarita and Passo Feio complexes
 864 (modified after Battisti, 2022). Possible scenarios for the magmatic events in the Dom Feliciano
 865 Belt central sector are drawn at the top left (ca. 800–770 Ma) and the middle right (600–580
 866 Ma).

867

868

869

870 **6. Conclusions**

871

872 New Sr-Nd isotopic data from metavolcanic rocks interleaved with
873 metasedimentary sequences of the Passo Feio and Porongos complexes, combined
874 with U-Pb zircon ages of acidic metavolcanic rocks from the Passo Feio Complex, were
875 performed. In addition, the new data were compared with meta-igneous data available
876 in the literature for the Passo Feio, Porongos, and Várzea do Capivarita complexes.
877 The results allow us to draw the following conclusions.

878 i) U-Pb LA-ICPMS zircon analyses in two acidic metavolcanic rocks from the
879 northern region of Passo Feio Complex yielded crystallisation age of the protolith at
880 580 ± 2 Ma (2σ).

881 ii) Magmatism in the Passo Feio, Porongos, and Várzea do Capivarita complexes
882 can be grouped into two diachronous magmatic events and three geochemical groups
883 plus one distinct sample.

884 The first magmatic event has happened at 810–780 Ma, in the Várzea do
885 Capivarita and Porongos complexes (both eastern and western regions). It is
886 represented by the rocks grouped in geochemical *Group 1*. The rocks of this pattern
887 represent magmatic associations produced from subduction-related sources, with
888 significant contribution of crustal materials, due to the crustal recycling and/or
889 assimilation of host rocks and crustal melts, based on geochemical arguments and
890 $^{87}\text{Sr}/^{86}\text{Sr}_{(790 \text{ Ma})}$ values higher than 0.715 and $\epsilon\text{Nd}_{(790 \text{ Ma})}$ mainly from -5 and -11 (up to
891 -22). The proposed geological scenario is an active continental margin, as in Andean-
892 type mature arcs. In the Porongos Complex, such rocks are part of the Cerro da Árvore
893 sequence.

894 The second period of magmatism extends from ca. 600 to 580 Ma and is
895 registered in the Passo Feio Complex and the western Porongos Complex. The
896 geochemical *groups 2 and 3* plus a basic metavolcanoclastic sample (*Bmvc*) are part
897 of this magmatism. According to the $^{87}\text{Sr}/^{86}\text{Sr}_{(580 \text{ Ma})}$ values of 0.7035–0.7050 and $\epsilon\text{Nd}_{(580 \text{ Ma})}$
898 values higher than -10, and elemental geochemistry, metavolcanic rocks of
899 *groups 2 and 3* were generated from a subduction-related enriched mantle, but without
900 major crustal contamination, as in a back-arc setting. However, for *Bmvc*, both
901 elemental and isotope ($^{87}\text{Sr}/^{86}\text{Sr}_{(600 \text{ Ma})} = 0.7065$; $\epsilon\text{Nd}_{(600 \text{ Ma})} = +1$) geochemistry
902 suggest a mantle-derived origin without significant contribution of subduction-related
903 sources, crustal melting and contamination. Such differences may indicate the

904 complexity of this Ediacaran magmatism (600-580 Ma) and demand further studies. In
905 the Porongos Complex, this magmatism is related to the Capané sequence.

906 iii) Our data comparison indicates a shared tectonic evolution between the Passo
907 Feio Complex and the western Porongos Complex (Capané sequence) at ca. 600–580
908 Ma, and also a shared tectonic evolution between the eastern Porongos Complex
909 (Cerro da Árvore sequence) and Várzea do Capivatira Complex at ca. 810–770 Ma.

1218 **Appendix**

1219

1220 **1 - Sm-Nd and Rb-Sr isotope analyses**

1221

1222 Sm-Nd and Rb-Sr isotope compositions analyses were carried out at the
1223 Institute of Geology of the Czech Academy of Sciences (IG CAS). Two additional
1224 analyses were investigated at the Laboratório de Geologia Isotópica, of the
1225 Universidade Federal do Rio Grande do Sul (LGI-UFRGS).

1226 At the Institute of Geology of the Czech Academy of Sciences (IG CAS),
1227 about 100 mg of sample was dissolved on a hot plate for ~72 hours at 140 °C in
1228 a mixture of 23 M HF and 7 M HNO₃ in the presence of an appropriate amount of
1229 mixed ¹⁵⁰Nd–¹⁴⁹Sm spike. Afterwards, the solution was dried down, re-dissolved
1230 several times using concentrated HCl and HNO₃, and finally dissolved in 2 ml of
1231 1 M HNO₃. Strontium, Sm, and Nd were extracted from the matrix using an ion-
1232 exchange chromatography procedure outlined in Pin et al. (2014). This includes
1233 Sr isolation by Sr.resin (Triskem, France) and Sm-Nd extraction by a combination
1234 of TRU and LN resins (both from Triskem, France). The isotopic analyses of Sr,
1235 Sm, and Nd were performed using the Thermo Triton Plus thermal ionisation
1236 mass spectrometer (TIMS, Thermo) housed at the IG CAS operated at static
1237 mode and using a Re single filament and Ta-activator for Sr and a double Re and
1238 Ta–Re filament assembly for Nd and Sm, respectively. Mass fractionation
1239 correction was performed using a ⁸⁸Sr/⁸⁶Sr = 8.3752, ¹⁴⁶Nd/¹⁴⁴Nd = 0.7219 and
1240 ¹⁴⁷Sm/¹⁵²Sm = 0.56081. The Sm and Nd concentrations were calculated by the
1241 isotope dilution method. The external reproducibility of Sr and Nd isotopic
1242 analyses was demonstrated by the long-term measurements of the NIST SRM
1243 987 yielding ⁸⁷Sr/⁸⁶Sr ratio of 0.710239 ± 0.000009 (2s, n = 4) and JNdi-1 with a
1244 determined ¹⁴³Nd/¹⁴⁴Nd value of 0.512104 ± 0.000007 (2s, n = 4).

1245 At the Laboratório de Geologia Isotópica (LGI-UFRGS), the samples were
1246 washed in 2.5 N HCl and then spiked with ¹⁴⁹Sm/¹⁵⁰Nd tracers and completely
1247 dissolved in HF, HNO₃ and HCl. Anionic LN-B50-A resin (100–150 µm) was used
1248 to separate Sm and Nd. Each element was collected, and afterwards, the
1249 samples were dried and loaded with 0.25 N H₃PO₄ on a single Ta (for Sm) and
1250 on a triple Ta-Re-Ta (for Nd) filament. The samples were run in a VG Sector 54
1251 multi-collector thermal ionisation mass spectrometer in static mode. Sr ratios
1252 were normalised to ⁸⁶Sr/⁸⁸Sr = 0.1194. Standard values of ⁸⁶Sr/⁸⁶Sr (SrCO₃ NBS-

1253 987 standard) are 0.71026 ± 0.000010 . Nd ratios were normalised to $^{146}\text{Nd}/^{144}\text{Nd}$
1254 = 0.7219. Standard values of $^{143}\text{Nd}/^{144}\text{Nd}$ (Nd_2O_3 LaJolla Nd standard) are
1255 0.511856 ± 0.000010 .

Table 1. Sm-Nd data for Porongos and Várzea do Capivarita complexes available in the literature (no data for the Passo Feio Complex).

EPC – Eastern region of Porongos Complex; WPC – Western region of Porongos Complex; VCC – Várzea do Capivarita Complex

Samples labelled as TM are from Martil et al. (2017); PM and K are from Gollmann et al. (2008); BR are from Saalman et al. (2006).

Data highlighted in *italic blue* are values recalculated that match with the available published data. Recalculated data that do not match are highlighted in **bold red**.

Errors reported as in the original papers. Neodymium crustal residence ages (TDM) were calculated following the depleted mantle model of DePaolo (1981).

$\epsilon\text{Nd}(t)$ values were recalculated using U-Pb zircon ages as reference. Original papers data are available as supplementary.

NPF – Northern region of Passo Feio Complex; SPF – Southern region of Passo Feio Complex; EPC – Eastern region of Porongos Complex; WPC – Western region of Porongos Complex
 Errors reported as in the original laboratories report. Neodymium crustal residence ages (TDM) were calculated following the depleted mantle model of De Paolo (1981). $^{87}\text{Sr}/^{86}\text{Sr}_{(t)}$ and $\epsilon\text{Nd}_{(t)}$ values were recalculated using U-Pb zircon ages as reference.

Table 5. Summary of the results obtained in this study (coordinates in UTM – fuse 22J – datum Córrego Alegre, 1984)

Errors are 1-sigma; Pb_c and Pb* indicate the common and radiogenic portions, respectively.

Error in Standard calibration was 0.23% (not included in above errors but required when comparing data from different mounts).

(1) Common Pb corrected using measured ²⁰⁴Pb.

Artigo 3

Figura S1. Imagens de catodoluminescência dos cristais de zircão estudados nas amostras MF-174A e MF-175A com idade ^{238}U – ^{206}Pb indicada. As diferentes cores dos pontos analisados foram utilizadas para distinguir as análises nos diagramas concórdia das figuras 4b e 5b.

Figura S2. Mapa com a localização das amostras de geoquímica discutidas neste artigo. Nas próximas páginas, mapas de detalhes das áreas indicadas são apresentados: a) Região oeste do Complexo Porongos (modificado de Hofig et al., 2018); (b) e (c) Região leste do Complexo Porongos (modificado de Battisti et al., 2018) e; d) Complexo Várzea do Capivarita (modificado de Martil et al., 2011). A legenda dos mapas de detalhe segue as do mapa principal, exceto quando indicado.

Figura S3. Localização das amostras discutidas no artigo: a) Região oeste do Complexo Porongos (Hofig et al., 2018, modificado); (b), (c) Região leste do Complexo Porongos (Battisti et al., 2018, modificado).

Figura S4. Localização das amostras discutidas no artigo: d) Complexo Várzea do Capivarita (modificado de Martil et al., 2011).

Tabela S3: Detalhes técnicos do equipamento utilizado para as análises U-PC por LA-ICPMS.

LA-ICP-MS U-(Th-)Pb data (reporting template according to Horstwood et al. 2016)	
Laboratory and Sample Preparation	
Laboratory name	Institute of Geology of the Czech Academy of Sciences, Prague, Czech Republic
Sample type/mineral	magmatic zircon
Sample preparation	Conventional mineral separation, 1 inch resin mount, 0.05 mm polish to finish
Imaging	CL, JEOL JXA-8530F Field Emission EPMA, Institute of Petrology and Structural Geology, Charles University in Prague
Laser ablation system	
Make, Model and type	Teledyne Cetac Analyte Excite laser
Ablation cell and volume	built-in 2- volume cell HelEx II, 100x100 mm
Laser wavelength (nm)	193 nm
Pulse width (ns)	< 4 ns
Fluence (J cm ⁻²)	3.5 J cm ⁻²
Repetition rate (Hz)	5 Hz
Ablation duration (s)	35 s
Spot diameter (mm)	25 mm
Sampling mode/pattern	Static spot ablation
Carrier gas	100% He + little addition N ₂ in the cell, Ar make-up gas combined using a Y-piece along the sample transport line to the torch.
Cell carrier gas flow (l min ⁻¹)	All gases and aerosole are mixed in the in-house glass signal homogenizer (design of <i>Tunheng and Hirata, 2004</i>) right before entering torch
N ₂ flow (ml min ⁻¹)	0.89 l min ⁻¹
Ar make-up gas flow (l min ⁻¹)	4.5 ml min ⁻¹
0.66 l min ⁻¹	
ICP-MS Instrument	
Make, Model and type	Thermo Scientific double-focusing magnetic sector field Element 2 HR-ICP-MS
Sample introduction	Dry ablation aerosol
RF power (W)	1200 W
Detection system	discrete dynode, dual mode secondary electron multiplier (SEM); analysis possible in 3 modes (cps-analog-both)
Masses measured (mode)	204 (cps), 206 (both), 207 (cps), 208 (cps), 232 (both), 235 (cps), 238 (both)
Integration time per peak/dwell times (ms)	204 (10 ms), 206 (15 ms), 207 (30 ms), 208 (10 ms), 232 (10 ms), 235 (20 ms), 238 (10 ms)
Total integration time per output data point (s)	~ 0.12 s (time resolution of the data)
Data Processing	
initial calculation	The accuracy of 238 mass measured in "both" mode is dependent on the correctly determined ACF (Analog Correction Factor). In order to correct for this variability, the data are pre-processed using a Python routine for decoding the Thermo Element ICPMS dat files (<i>Hartman et al., 2017</i>) and an in-house Excel macro. As a result, the intensities of 238 are left unchanged if measured in a counting mode and recalculated from 235U intensities (using the natural 138U/135U of 137.818) in all cases the 238U was acquired in analog mode, thus eliminating the non-linearity between pulse counting and analog detecting modes.
Gas blank	15 s on-peak zero subtracted
Calibration strategy	Plešovice used as primary reference material, 91500 and GJ1 used as secondaries/validation
Reference Material information, reference age	Plešovice (<i>Sláma et al. 2008</i>), 337 Ma (Concordia age); 91500 (<i>Wiedenbeck et al. 1995</i>), 1065 Ma (Concordia age); GJ1 (<i>Jackson et al. 2004</i>), 609 Ma (206Pb/207Pb age)
Data processing package used/Correction for LIEF	lilite v3.5 software (<i>Paton et al. 2010</i>) with the VizualAge utility (<i>Petrus and Kamber, 2012</i>) used for data normalisation, uncertainty propagation and export blank intensities and instrumental bias interpolated using an automatic spline function; down-hole inter-element fractionation (LIEF) corrected using an exponential function LIEF correction assumes reference material and samples behave identically Isoplot v4_16 (<i>Ludwig, 2008</i>) used for pooled age uncertainty propagation, age calculation and plotting.
Common-Pb correction, composition and uncertainty	No common-Pb correction applied to the data
Uncertainty level and propagation	Ages are quoted at 2s absolute, propagation is by quadratic addition.
Quality control/Validation	Reproducibility and age uncertainty of reference material are propagated where appropriate following the recommendation of <i>Horstwood et al. (2016)</i>
Other information	91500 – Concordia age = 1061 ± 8 Ma (2s, MSWD = 0.95, n = 14). GJ-1 – Wtd ave 206Pb/238U age = 604 ± 6 (2s, MSWD = 0.8, n = 14). Systematic uncertainty for propagation is 2% (2s).
20 s wait time between ablations.

Abstract

The lower crust is, on average, mafic in composition and composed of minerals that remain mechanically strong up to high temperatures. Here we show that dissolution-precipitation creep (as a type of diffusion creep) plays a major role in deformation of gabbro bodies at upper amphibolite facies conditions. The Kågen gabbro, N. Norway, is comprised of undeformed gabbro lenses enclosed by mylonitised margins that deformed at 690 ± 25 °C and 1.0 to 1.1 GPa. The evolution of the microstructures and fabric of the low strain gabbro to high strain margins were investigated. Original clinopyroxene and plagioclase dissolved during mineral reactions and precipitated as new mineral phases: new plagioclase and clinopyroxene (different compositions relative to the magmatic parents) and additional amphibole and garnet. Microstructural and crystallographic preferred orientation (CPO) data indicate that dissolution-precipitation creep is the dominant deformation mechanism. Amphibole shows a strong CPO that is primarily controlled by orientated growth in the stretching direction. The progression of mineral reactions and weakening is directly connected to a fluid-assisted transformation process that facilitates diffusion creep deformation of strong minerals at far lower stresses and temperatures than required by dislocation creep. Initially strong lithologies can become weak, provided that reactions proceed during deformation.

<p>O presente trabalho teve como objetivo investigar a história evolutiva pré-colisional e colisional do domínio central do Cinturão Dom Feliciano, a partir da relação temporal e espacial dos Complexos Porongos, Várzea do Capivarita e Passo Feio utilizando uma abordagem detalhada com metodologias distintas. A história pré-colisional do Cinturão Dom Feliciano foi investigada a partir de geocronologia U-Pb utilizada para determinar a idade de cristalização magmática de litotipos do Complexo Varzea do Capivarita e Complexo Porongos, e proveniência de rocha metassedimentar do Complexo Varzea do Capivarita e isótopos de oxigênio. A história colisional foi investigada utilizando uma abordagem petrocronológica utilizando datação U-Pb SIMS em monazita, Lu-Hf rocha-total em granada aliada com o cálculo de pseudosseções para delimitar as condições P-T em rochas metassedimentares dos Complexos Porongos e Passo Feio. Dados de geoquímica de rocha-total, isótopos de Sr e Nd e geocronologia U-Pb LA-ICP-MS em zircão em litotipos do Complexo Passo Feio foram utilizados para elucidar questões relacionadas ao ambiente tectônico e estabelecer as possíveis relações entre os complexos Porongos, Varzea do Capivarita e Passo Feio. A presente tese é apresentada na forma de três artigos submetidos a revistas internacionais de grande prestígio na literatura internacional, todas com conceito A1. O trabalho está bem organizado, bem escrito e demonstra bastante maturidade do candidato com relação ao seu tema de pesquisa, e atesta que os objetivos centrais do trabalho foram alcançados com sucesso. Encaminho um pdf comentado da tese, com alguns comentários referentes à apresentação e tratamento dos dados, que podem influenciar na interpretação de parte dos dados petrológicos e geocronológicos, e que podem auxiliar na etapa de revisão dos artigos submetidos.</p>

<p>A tese de doutorado do aluno Matheus Ariel Battisti é constituída de 3 artigos submetidos em revistas internacionais, com resultados inéditos sobre rochas da região central e oeste do CDF. Os três artigos estão muito bem organizados, com descrições detalhadas e interpretações pertinentes.</p> <p>Algumas questões ficaram em aberto e devem ser revisadas, tais como: empilhamento vertical do CVC sob o CP implicaria em idades um pouco mais antigas do CVC, considerando que ele também apresenta evidências de magmatismo sin-sedimentação, considero mais adequado colocá-lo lado a lado durante o <u>evento sedimentar</u>. Revisar ao longo do texto a localização das unidades segundo a subdivisão do CDF (ex: CVC seria Domínio Central ou Leste?, no artigo 3 até o CPF acabou entrando no central). Rever a aplicabilidade do conceito de <i>Hinterland</i> e <i>Foreland</i>. Avaliar se o magmatismo tem características de magmatismo Adakítico, caso contrário indicar a fusão proveniente da cunha do manto astenosférico (Figuras dos modelos geológicos). Sugiro fundir o texto do Lu-Hf em granada+elementos traços com o texto sobre a monazita (Artigo 2) para viabilizar as <i>plates</i> com informações de ambos os temas. No mesmo artigo, colocar metodologia utilizada nas análises Lu-Hf em granada. No artigo 3, fazer um teste com amostras com menor % de sílica possível, para posterior comparação entre elas. Sugiro normalizar os dados do diagrama multielementar para manto primitivo, o que facilita a comparação quando se trabalha com ambientes tectônicos diferentes. No diagrama Harker, não vejo necessidade de relacionar a cor com a quantidade de SiO₂, considerando que essa informação já consta no eixo x. Na figura 14 do terceiro artigo, sugiro substituir pré-orogênico por pré-colisional e adicionar a informação no texto de qual arco estaria relacionado ao <i>back arc</i> (ca. 600-580 Ma magmatism).</p> <p>Por fim, gostaria de enfatizar que o trabalho adiciona novos e importantes dados para distintos eventos geológicos que ocorreram ao longo de paleobacias da região central e oeste do CDF e seus magmas associados. Esses dados serão essenciais para a evolução dos conhecimentos acerca da história geológica do</p>

CDF no RS.

PARECER:

The thesis of Matheus Ariel Battisti is well-written and organized, and presents a novel and large database of analytical data focused on petrological, geochemical and petrochronological constraints on the Neoproterozoic evolution of the central Dom Feliciano Belt. The quality of the data and their analysis is thoroughful, particularly when integrating new data with those of the literature. As far as I'm concerned, the outcomes of the geochronological (U-Pb zircon) and coupled thermobarometric-petrochronological data (P-T-t) are particularly relevant, since they reveal the existence of multiple tectonometamorphic and magmatic events in the Dom Feliciano Belt. Based on all aforementioned aspects, I consider this work as highly outstanding.
